# 1 Introduction

## 2 Infinite Conductivity in Translation Invariant Systems

Ever since Drude published his theory about the electrical conductivity in metals [Dru00] at the beginning of the last century it is well known that non-conservation of electron momentum in a system is required for finite electrical conductivity. In Drude's model the electrons possess a mean scattering time  $\tau_{\text{el}}$ , which represents the mean time between two scattering events of an electron and a lattice atom. At each scattering event the electrons transfer momentum to the lattice atoms, which is the reason electron momentum isn't a conserved quantity. In the case of conserved momentum an applied electrical field, for example, is accelerated the electrons up to an infinite velocity, by what an infinite conductivity is eventuated.

In the following a momentum conserving system is considered and the electrical conductivity is computed using the memory-matrix-formalism, where an infinite conductivity is expected. Therefore firstly a short overview over the memory-matrix-formalism is given, where a detailed and explicit deviations follows in chapter 5.

### 2.1 An Overview over the Memory-Matrix-Formalism

Let us assume a physical dynamical variable  $A(t)$  in an arbitrary system and an arbitrary perturbation too. Our interest is now the time evolution of  $A(t)$  depending on the perturbation. Completely general, a physical dynamical variable can be splitted into two parts, a secular one and a non-secular one, which is shown in [Mor65]. The latter represent processes like fluctuations or initial transient processes, which have in common a short lifetime comparing to the secular processes. The dynamic and time evolution of  $A(t)$  is therefore dominated by secular processes.

This separation enables a simple but clever and intelligent geometrical interpretation, where dynamical variables are considered as vectors in a vector space. Thereby the variables of the unperturbed system represent the basis vectors of this vector space, denoting in the case of the variable  $A(t)$  as A-axis. Due to perturbation the direction of the variable  $A(t)$  changes with respect to the A-axis. The projection of  $A(t)$  onto the A-axis corresponds to the secular part, where the perpendicular component represents accordingly the non-secular parts.

First of all the mathematical framework has to be considered. In quantum mechanics the Liouville space, also called as operator space, is the respective vector space of the memory-matrix-formalism. Like the name operator space should supposed the vectors of the Liouville space are operators, which are certainly Hermitian. The basis of the Liouville space is signified as  $\{|A_i\rangle\}$ , where  $i = 1, 2, 3, \dots, n$ , and the corresponding

dual space basis is denoted as  $\{|A_i\rangle\}$ . To make the definition of any vector space complete a scalar product is required, where the following one is chosen.

$$(|A_i(t)|A_j(t')) = \frac{1}{\beta} \int_0^\beta d\lambda \langle A_i^\dagger(t) A_j(t' + i\lambda) \rangle \quad (2.1)$$

The normal time evolution  $A_i(t) = e^{iHt/\hbar} A_i(0) e^{-iHt/\hbar}$  of an operator should be valid so that  $A_i(i\lambda) = e^{-\lambda H} A_i(0) e^{\lambda H}$  can be used. The choice of the scalar product is determined under the aspect that as a consequence the time evolution of  $A(t)$  given the most probably path, if secular processes are neglected, see [Mor65]. In quantum mechanics the dynamic of an operator is ususally described by the Heisenberg equation of motion, which is transformed using the dyad product into the Liouville space.

$$|\dot{A}_i(t)\rangle = \frac{i}{\hbar} |[H, A_i(t)]\rangle = iL|A_i(t)\rangle \quad (2.2)$$

where the Hermitian Liouville operator,  $L = \hbar^{-1}[H, \bullet]$ , is introduced, which is defined by acting onto an arbitrary operator. The formal solution of this equation is given by  $|A_i(t)\rangle = \exp(itL) \cdot |A_i(0)\rangle$ , where the time evolution of an operator is therefore given by the Liouville operator. In reference to the secular part in a pertubated system a projection operator is defined in the Liouville space. Starting therefore with a set of arbitrary operators  $\{C_i\}$ . The choice of the operators is different for each investigated problem and unimportant at the moment. The definition of the projection operator in Liouville space follows directly from the projection operator defined in the usually used Hilbert space in quantum mechanics.

$$P = \sum_{i,j} \frac{|C_i(0)\rangle \langle C_j(0)|}{(C_i(0)|C_j(0))} \quad (2.3)$$

If the projection operator acting on some vector in Liouville space yields the projection onto the subspace spanned by the operator  $C_i$  and thus the operator  $Q = 1 - P$  yields the corresponding part projected out of the subspace. Further the projection operator is Hermitian and fullfills the two properties  $P^2 = P$  and  $PQ = QP = 0$ . This completes the required mathematical basis of the memory-matrix formalism.

Correlation functions are the natural approach describing the reaction of a dynamic variable on a perturbation. In quantum mechanics the correlation function is defined in Kubo's linear response theory as an integral over an expectation value of two operators, where one of them is certainly the investigated operator and the other one is the coupling operator from the perturbation Hamiltonian. In the Liouville space the correlation function is defined as

$$c_{ij}(t) := (A_i(t)|A_j(0)) = \frac{1}{\beta} \int_0^\beta d\lambda \langle A_i^\dagger(t) A_j(i\lambda\hbar) \rangle, \quad (2.4)$$

where in the second step the definition of the scalar product (2.1) is only used. Expressing the time evolution of  $A_i(t)$  with the Liouville operator, using the Laplace transformation and a few conversions yield a algebraic matrix equation of the correlation function, which has the form

$$\sum_l \left[ \omega \delta_{il} - \Omega_{il} + i \Sigma_{il}(\omega) \right] \mathcal{C}_{lj}(\omega) = \frac{i}{\beta} \chi_{ij}(0), \quad (2.5)$$

where the abbreviations

$$\Omega_{il} := i\beta \sum_k (\dot{A}_i | C_k) \chi_{kl}^{-1}(0) \quad \text{and} \quad \Sigma_{il}(\omega) := i\beta \sum_k (\dot{A}_i | Q \frac{1}{\omega - QLQ} Q | \dot{C}_k) \chi_{kl}^{-1}(0) \quad (2.6)$$

are introduced. Both sums over  $l$  and  $k$  runs over the set of operators, defined by the projection operator. Similarly the indices  $i$  and  $j$  has to be chosen out of this set of operators, so that (2.5) yields  $n^2$  equations, if  $n$  is the number of operators in the set. Both abbreviations can be combine to a function  $M_{il}(\omega) := \Sigma_{il}(\omega) + i\Omega_{il}$ , called the memory function. Thereby  $\Sigma_{il}(\omega)$  takes the role of the quantum mechanical self energy and on the other hand  $\Omega_{il}$  represents dissipative effects. In the case of an invariant Hamiltonian with respect to time reversal symmetry and that the operators  $A_i$  and  $C_k$  of the expectation value in  $\Omega_{il}$  have same signature under time reversal symmetry  $\Omega_{il}$  vanishes. This assertion is proven in great detail in 5.3.1. Thus the memory function is solely determined by  $\Sigma_{il}(\omega)$ .

The structur of  $\Sigma_{il}(\omega)$  remembers to the one of the Laplace transformed correlation function, comparing equation (5.45). Two things are different. The expectation value is performed with respect to the operators like  $Q|\dot{A}_i)$  instead of  $|A_i)$  and on the other hand only the reduced Liouville operator  $QLQ$  is considered. The latter projects at the part of the full Liouville operator, which causes the intrinsic fluctuations of the operator  $A$ . In other words the operator  $QLQ$  describes the internal dynamics of all other degrees of freedom of the system, called the "bath", excluded  $A$ . The coupling to the bath is characterized by the vector  $Q|\dot{A}_i)$ . The coupling to the bath is clearly changing the dynamic behaviour of  $A$ .

## 2.2 Electrical Conductivity in a Momentum Conserving System

In the following with the aim of the memory-matrix-formalism the electrical conductivity is computed for a system, where momentum is conserved. Therefore an infinite conductivity is expected due to the fact that electrons does not transfer any momentum to other degrees of freedom. Besides conserving momentum the observed system has to statisfy some additional requirements. Firstly the current has to be an unconserved quantitiy. Further the scalar product  $(J|P)$  between current and momentum has to be non-zero. In other words both quantities possess a finite overlap. These two

quantities should also generated the subspace into the projection operator projects. Remember the sum in (2.3) summerizes over all operators  $C_i$ , where the choice of them is different to each proplem and has to be done with respect to the investigated quantity, which is in our case the electrical conductivity. The electrical conductivity is determined by momentum and current, why we chosen them as our operators. Additionally the Hamiltonian has to be invariant under time reversal symmetry, which is our last requirement.

Nevertheless one remerk has to be done for computing the conductivity. Due to the fact that the Hamiltonian is invariant under time reversal symmetry and the subspace is generated by  $J$  and  $P$ , which have same signature under time reversal symmetry, no dissipative effects exist. The quantity  $\Omega$ , defined in (2.6), is therefore zero.

Purely general the electrical conductivity is given by the current-current correlation function  $\mathcal{C}_{JJ}(\omega)$ , see [Czy17]. The static case is obtained by taking the small freuquency limit,  $\omega \rightarrow 0$ , of the conductivity.

$$\sigma_{dc} = \lim_{\omega \rightarrow 0} \sigma(\omega) = \lim_{\omega \rightarrow 0} \beta \mathcal{C}_{JJ}(\omega) \quad (2.7)$$

The current-current correlation function is given by equation (2.5), which is in the case of the J-P subspace a  $2 \times 2$  matrix equation. The quantity  $\Sigma$  is simplified by two aspects. Firstly the momentum is conserved, which means the time derivative of  $P$  is zero and therefore all expectation values are trivially zero where  $\dot{P}$  is a taken vector. The remaining expectation values of  $\Sigma$  contains only the current  $J$ , but these ones vanishing too. The operator  $QLQ$  describes the intrinsic fluctuation of  $|J\rangle$ , which are assumed to be zero. Further the operator  $Q$  acting on  $|J\rangle$  yields the coupling to these intrinsic fluctuation and therefore  $Q|J\rangle = 0$ . The obtained matrix equation has a very simple form and the current-current correlation function can be directly readed out as

$$\mathcal{C}_{JJ}(z) = \frac{i}{\omega} \beta^{-1} \chi_{JJ}(\omega = 0) = \frac{i}{\omega} \mathcal{C}_{JJ}(t = 0), \quad (2.8)$$

where relation (5.43) is used. The correlation function at time  $t = 0$  is given by the scalar product  $\langle J(0)|J(0)\rangle$ , see (2.4). Due to the fact that current and momentum are two closely connected quantities this is also valid for their correlation functions, why the current-current correlation function is expresed with respect to the momentum-momentum correlation function as next.

Nothing or nobody bars us seperating the vector operator  $|J(0)\rangle$  into two pieces, one parallel and one perpendicular part, which are labeled as  $|J_{\parallel}\rangle$  and  $|J_{\perp}\rangle$ , respectively. How we learned above every variable generally consists of a secular and non-secular part, which doesn't mean that both parts actually exist in the observing model. The non-secular part is represented by the perpendicular component of  $|J\rangle$ . In the experiement these processes are obseved as a constant slowly fluctuating background, known as noise. Apart from this the secular part is represented by the parallel component of  $|J\rangle$  which is responsible for the electrical conductivity and is visable as the peak in the measurement, see 2.1.

Drude's theory of conductivity yields a direct proportionality between  $J$  and  $P$ , see [GM14] for example. Since momentum is conserved and current is unconserved in the

Figure 2.1: caption

investigated system this proportionality can't be valid. Nevertheless, remember, both quantities possess a finite overlap, which means that a part of the current is conserved and therefore parallel to the momentum. This part is the parallel component of  $\mathbf{J}$  and given by the projection von  $|\mathbf{J}\rangle$  onto  $|\mathbf{P}\rangle$ .

$$|\mathbf{J}_{\parallel}\rangle = \mathcal{P}|\mathbf{J}\rangle = \frac{|\mathbf{P}\rangle\langle\mathbf{P}|}{\langle\mathbf{P}|\mathbf{P}\rangle}|\mathbf{J}\rangle = \frac{\chi_{\mathbf{PJ}}}{\chi_{\mathbf{PP}}}|\mathbf{P}\rangle \quad (2.9)$$

Separating both current operator in  $\langle\mathbf{J}(0)|\mathbf{J}(0)\rangle$  yields four new correlation functions, where the mixed ones are zero, since  $|\mathbf{J}_{\parallel}\rangle$  and  $|\mathbf{J}_{\perp}\rangle$  are perpendicular to each other by construction. For the operators in the parallel correlation function  $\langle\mathbf{J}_{\parallel}(0)|\mathbf{J}_{\parallel}(0)\rangle$  equation (2.9) is used. Thereby the correlation function of the parallel components is represented as a momentum-momentum correlation function. Inserting the obtained expression for the current-current correlation function in (2.8) the conductivity is given by

$$\sigma(\omega) = \frac{|\chi_{\mathbf{PJ}}|^2}{|\chi_{\mathbf{PP}}|} \frac{i}{\omega} + \sigma_{\text{reg}}(\omega), \quad (2.10)$$

where the momentum-momentum correlation function is expressed as static susceptibility, see (5.43), and the regular conductivity  $\sigma_{\text{reg}}(\omega) = i(\omega\beta)^{-1}\langle\mathbf{J}_{\perp}|\mathbf{J}_{\perp}\rangle$  is introduced, which represents the noise, see 2.1.

In the above equation the quantity  $\omega$  is a complex number. For a physical interpretation  $\omega$  has to be a real number, why it is transformed on the real axis using analytical continuation, which means  $\omega \rightarrow \omega + i\eta$ , where  $\omega$  is real and the limit  $\eta \rightarrow 0^+$  is implied. The conductivity is then given by

$$\sigma(\omega) = \frac{|\chi_{\mathbf{PJ}}|^2}{|\chi_{\mathbf{PP}}|} \left( \text{P.V.} \frac{i}{\omega} + \pi\delta(\omega) \right) + \sigma_{\text{reg}}(\omega) \quad (2.11)$$

where  $\frac{1}{\omega+i\eta} = \text{P.V.} \cdot \frac{1}{\omega} - i\pi\delta(\omega)$  is used and P.V. symbolizes the prinzipel value. Taking now the small frequency limit  $\omega \rightarrow 0$  the  $\delta$ -distribution is the dominant term and the static conductivity becomes infinite, which is the exactly expected result. The static electrical conductivity is infinite in a momentum conserving system, thus conductivity is getting finite if the momentum isn't anymore a conserved quantity. The respertive underlying symmetry is translation symmetry. For breaking this symmerty many possibilities are available, but in the following computation only one of them, namely umklapp scattering, is considered. In the next chapter the observed spin-fermion model and the pertubation is introduced.

## 3 Spin-Fermion-Model

In the following chapter the spin-fermion-model for a metal exhibiting an antiferromagnetic quantum phase transition is introduced as presented in [ACS03]. Beside fermionic particle-hole-excitations in the vicinity of the quantum critical point bosonic spin fluctuations arise in this low energy theory, which enable an attractive interaction between electrons. This chapter isn't displaying a detailed mathematical or microscopic derivation of the spin-fermion-model, but rather it is based on a qualitative description to justify its form. For that a short overview over quantum phase transitions is established as suggested in [Sac11]. In particular, we focus one's attention on the arising spin fluctuations, argue they carry large momenta and introduce the damped spin density propagator and their periodicity. Further we present the basic concepts of hot-spot theory, which are points on the Fermi surface in 2D emerged since the magnetic Brillouin zone cuts the Fermi surface. Besides we review explicitly the conservation of momentum and non-conservation of current for the observing Hamiltonian. For breaking translation symmetry umklapp scattering is introduced and we prove that this is unconserving momentum.

### 3.1 The Spin-Fermion-Model at the Onset of the Antiferromagnetic Quantum Phase Transition

Many metals exhibit an antiferromagnetic phase transition at a characteristic temperature  $T_N$ , called Néel-temperature. The random ordered spins of lattice atoms ordering in consequence of thermal fluctuations along one axis, where the nearest neighbors are always aligned in opposite direction. This temperature can be changed by tuning a certain parameter like pressure or doping, for example. A schematic and simplified phase diagram is depicted in figure 3.1. Decreasing temperature the phase line between both magnetic phases reach a certain value for the tuning parameter  $g$  at  $T = 0$ , labeled with  $g_c$ . This point is called quantum critical point and in comparison with the phase transition at finite temperature quantum fluctuations are the origin of this phase transition.

Before starting with a qualitative derivation of the spin-fermion-model a short and rudimentary description of quantum phase transition is given. This overview is required for the analytical discussion of our computation later. However, the reason for phase transitions is always level crossing between the ground and an excited state. Due to the fact that level crossing is forbidden a band gap  $\Delta$  arises. This band gap is therefore a characteristic energy scale of the quantum phase transition. Considering only phase transitions of second order the characteristic energy scale  $\Delta$  is proportional

Figure 3.1: This figure shows a schematic and simplified phase diagram for metals transition from a paramagnetic (PM) into an antiferromagnetic (AFM) phase depending on a tuning parameter  $g$ . The phase line of the AFM phase ends decreasing temperature down to  $T = 0$  in a quantum critical point (QCP) at  $g = g_c$ . At this point the phase transition is only caused by quantum fluctuations. At  $T > 0$  thermal fluctuations more and more dominates the phase transition. Nevertheless quantum fluctuations influences the physical behaviour in a large regime, labeled as quantum critical phase.

to the tuning parameter as

$$\Delta \sim J|g - g_c|^{z\nu}, \quad (3.1)$$

where  $z\nu$  is a critical exponent and  $J$  a energy scale of a microscopic coupling [Sac11]. Beside a characteristic energy scale quantum phase transitions also possesses a characteristic length scale  $\xi$ , called correlation length, which diverges right at the quantum critical point.

$$\xi^{-1} \sim \Lambda|g - g_c|^\nu, \quad (3.2)$$

where  $\nu$  is again a critical exponent and  $\Lambda$  an arbitrary inverse length scale like a momentum cut-off, for example. Inserting (3.2) in (3.1) yields a directly relation between both characteristic quantities. For finite temperatures,  $T > 0$ , a second energy scale is given by  $k_B T$ , where  $k_B$  is the Boltzmann constant. Comparing both energy scales yields a proportionality between temperature and correlation length as

$$T \sim \xi^{-z}. \quad (3.3)$$

Further this explains the curved conical boundary phase lines of the quantum critical phase in figure 3.1. In the case of small temperatures the critical exponent  $z$  attains the value  $z = 2$ , so that the phase lines are shaped like a square root. Increasing temperature the phase boundary lines are linear, since the critical exponent changing to  $z = 1$  [PS14]. Inside this regime the physical behaviour of the metals is determined by quantum fluctuations.

Knowing the physical origin of quantum phase transitions the spin-fermion-model can be introduced. Instead of an microscopic and detailed mathematical description we want focus our introduction on qualitative arguments motivating the model. The spin-fermion-model describes metals in the vicinity of a magnetic quantum critical point considering fermionic quasiparticles and bosonic spin density waves. Thereby, the propagator is determined by the usual free fermionic Green function. Spin fluctuations are constituted as collective modes and their propagator is characterized by the dynamical magnetic susceptibility.

$$\mathcal{D}_\mu(\mathbf{q}, \omega) = \sum_{\mathbf{Q}} \frac{1}{(\mathbf{q} + \mathbf{Q})^2 + \xi^{-2} - (\omega/v_S)^2}, \quad (3.4)$$

where  $\mu$  is the spatial direction of the spin density wave,  $\xi$  the magnetic correlation length and  $v_S$  the spin wave velocity. The spin wave velocity is of the same order as the Fermi velocity since spin fluctuations originate due to fermions in the vicinity of the Fermi surface. Furthermore, the magnetic susceptibility possesses a peak at the momentum vector  $\mathbf{Q} = (\pi, \pi)$ . This implicates a strong coupling interaction between momentum vectors  $\mathbf{k}$  and  $\mathbf{k} + \mathbf{Q}$ .

Phase transitions are always associated by an order parameter equally the investigated antiferromagnetic phase transition, where the local magnetization measured by the spin expectation value  $\langle \mathbf{S}(\mathbf{r}_i) \rangle$  is the corresponding order parameter. Naturally, we have to summerarize over all spins located at a certain position  $\mathbf{r}_i$ . The order parameter is finite in the antiferromagnetic ordered phase and reaches zero in the paramagnetic disordered phase. Further, the expectation value of the spin operator is spatially modulated according to  $\langle S_\mu \rangle \sim \exp(i\mathbf{Q}\mathbf{R})$ , where  $\mathbf{R}$  is some lattice vector [Wei15], and therefore the order parameter and equally the propagator are periodical quantities. In reciprocal space this is reflected in the periodicity of the magnetic Brillouin zone spanned by the vector  $\mathbf{Q}$ .

Our description of the antiferromagnetic quantum phase transition in the spin-fermion-model is based on a few fundamental assumptions, comparatively to [ACS03]. We assume spin fluctuations arise over a large range of the tuning parameter and, furthermore, other low-energy collective degrees of freedom, independent on spin excitations, are neglectable. Starting by large values of the tuning parameter  $g$  in the paramagnetic phase, the physical behaviour is described by Landau's Fermi liquid theory. Decreasing the tuning parameter and getting closer to the quantum critical point changes the behaviour to a the Non-Fermi liquid. Assuming only one type of fermions the arising collective modes are originated due to permanent interaction between particles and holes. These bosonic spin excitations determine the physics in the vicinity of the

quantum critical point and turning into smooth modes. Therefore, we assume that only one dominant channel exist for fermion-fermion interaction with energies smaller than a certain energy cut-off  $\Lambda$ . Further we introduce on collective spin mode which contains this interaction.

In the vicinity of the quantum critical point the (magnetic) correlation length  $\xi$  and the coupling constant  $\lambda$  diverges. Therefore the correlation length is much larger than the lattice constant,  $\xi \gg a$ , and the coupling constant is much larger than the band gap,  $\lambda g g \Delta$ , where the band gap is associated with the energy of spin excitations. In the limit of large distance and small energies/temperatures a microscopic consideration of the lattice Hamiltonian is unnecessary. In this low-energy theory spin fluctuations are described as a three component bosonic field  $\Phi_\mu(\mathbf{x}, \tau)$  defined as a sum over all spin operators analysed in the neighbourhood of the spin's site  $i$ ,  $\Phi_\mu(\mathbf{x}, \tau) \sim \sum_{i \in \Gamma(\mathbf{r}_i)} S_\mu(\mathbf{r}_i)$ , where  $\mu$  is the spatial direction of the field and  $\Gamma(\mathbf{r}_i)$  represent the neighbourhood around the spin position  $\mathbf{r}_i$  [Sac11]. The magnitude of the bosonic field is chosen arbitrary and the field itself is considered as a real field. The obtained effective Hamiltonian for spin fluctuations in the low-energy theory is then given by

$$H_\Phi = \sum_\mu \int_{\mathbf{k}} \left[ -\frac{\mathbf{k}^2}{2} - \frac{r}{2} \right] \Phi_\mu(\mathbf{k}, \tau) \Phi_\mu(-\mathbf{k}, \tau) + \frac{v_S^2}{2} \pi_\mu(\mathbf{k}, \tau) \pi_\mu(-\mathbf{k}, \tau), \quad (3.5)$$

where  $r$  is a control parameter and corresponds to the squared inverse correlation length,  $r = \xi^{-2}$ . The integral is extended over the first Brillouin zone and the sum runs over the spatial direction of the bosonic field.

Further we have to take into account that the spin density waves are damped in consequence of the interaction with fermions. The spin itself doesn't possess an own damping source. The whole damping is governed by decaying of particle-holes-pairs and the full renormalized particle-hole bubble corresponds to the inverse lifetime of spin fluctuations. The interaction Hamiltonian between spin density waves and fermions is given by

$$H_{\Psi\Phi} = -\lambda \sum_\mu \int_{\mathbf{k}} \int_{\mathbf{q}} \Phi_\mu(\mathbf{k} - \mathbf{q}, \tau) \left[ \Psi_a^\dagger(\mathbf{k}, \tau) \cdot \sigma_\mu \cdot \Psi_b(\mathbf{q}, \tau) + \Psi_b^\dagger(\mathbf{k}, \tau) \cdot \sigma_\mu \cdot \Psi_a(\mathbf{q}, \tau) \right], \quad (3.6)$$

where  $\lambda$  is the coupling constant, both integrals are extended over the first Brillouin zone and the sum runs over all spatial directions of the bosonic field.  $\sigma_\mu$  is the Pauli matrix with respect to the spatial direction and the index a and b at the fermionic fields  $\Psi$  represent the two different Fermi surfaces in the obtained model which is explained below presently. The imaginary part of the susceptibility has to be computed in the low-energy limit with the tools of the quantum field perturbation theory. An explicit calculation is presented in the appendix ???. Further, assuming the dynamic of the spin fluctuations is governed by the low-energy fermions the  $\omega^2$ -term in the susceptibility (3.4) is neglectable [ACS03] and at the vicinity of the quantum critical point the correlation length diverges, so  $\xi^{-2} \rightarrow 0$ . Then the damped magnetic susceptibility is

Figure 3.2: On the left hand side the Brillouin zone is depicted containing the Fermi surface of both species of fermions,  $\tilde{\Psi}_a$  and  $\tilde{\Psi}_b$ . While the fermions  $\tilde{\Psi}_a$  are located with an anisotropic parapolical dispersion at the origin  $(0,0)$ , the fermions  $\tilde{\Psi}_b$  are located with a  $\pi/2$ -rotated anisotropic parapolical dispersion at the corners of the Brillouin zone,  $(\pi, \pi)$  for example. The vector  $\mathbf{Q}$  connects certain points on the Fermi surface, called hotspots and represented with dots. As a result of this an attraction between these fermions occurs. On the right hand side the fermions  $\tilde{\Psi}_a$  are shifted to the corner at  $(\pi, \pi)$ . The convenience of this representation is that the coupling between fermions and spin fluctuations is local and independent of the position.

then given by

$$\mathcal{D}_\mu(\mathbf{q}, i\omega_n) = \sum_{\mathbf{Q}} \frac{1}{(\mathbf{q} + \mathbf{Q})^2 + \gamma|\omega_n|}, \quad (3.7)$$

where  $\omega_n$  represent the bosonic Matsubara frequency. Due to the fact that damping of spin fluctuations is strongly connected to fermions there are no independent degrees of freedom. The damped susceptibility constitutes the interaction between fermions on the Fermi surface separated by the large vector  $\mathbf{Q}$ . These points on the Fermi surface are labeled as hot-spots in two dimensions, which we want to discuss next. In comparison to a normal metal these new interactions of spin fluctuations separate the Fermi surface into "hot" and "cold" manifolds. Considering a point  $\mathbf{k}$  on the Fermi surface of a  $d$ -dimensional system, so the fermion has zero energy. The spin density wave connects this point to another point  $\mathbf{k} + \mathbf{Q}$ . We require that this point has to be also on the Fermi surface, which is our second constraint. Both constraints yield a  $d - 2$ -dimension manifold for a  $d$ -dimensional system. In the case of  $d = 2$  the "hot" manifold is called a hot-spot. Another visualization of "hot" manifolds offers the magnetic Brillouin zone spanned by the vector  $\mathbf{Q}$ . The intersections of the magnetic Brillouin zone and the Fermi surface are equivalent to the "hot" manifolds.

In our investigated model the fermions are considered as free up to the interaction

with the spin fluctuations. We assume two species of fermions,  $\tilde{\Psi}_a$  and  $\tilde{\Psi}_b$ , with an anisotropic parabolic dispersion, as suggested in [PS14] and depicted on the left hand side in figure 3.2. This isn't a discrepancy to our previous constraint, assuming one fermion since both species of fermions are electrons and differ only in their dispersion. The fermions  $\tilde{\Psi}_a$  and  $\tilde{\Psi}_b$  are located on an ellipse around the origin  $(0,0)$  and  $(\pi,\pi)$ , respectively. Both ellipses are separated by the vector  $\mathbf{Q} = (\pi,\pi)$  and rotated by  $\pi/2$  to each other. For achieving a continuum theory the ellipse centered around  $(\pi,\pi)$  is shifted by the vector  $\mathbf{Q}$  to the origin. Therefore new fermionic fields,  $\tilde{\Psi}_a(\mathbf{r}) = \Psi_a(\mathbf{r})$  and  $\tilde{\Psi}_b(\mathbf{r}) = \Psi_b(\mathbf{r}) \exp(i\mathbf{Q}\mathbf{r})$ , are introduced. The new dispersion of the fermions  $\Psi_a(\mathbf{r})$  and  $\Psi_b(\mathbf{r})$  is depicted on the right hand side in figure 3.2. The enormous advantage is that the coupling between the fermions caused by spin density waves is local and independent of the position. In reciprocal space, the free continuum Hamiltonian of the fermions  $\Psi_a(\mathbf{r})$  and  $\Psi_b(\mathbf{r})$  is given by

$$H_\Psi = \int_{\mathbf{k}} \left[ \epsilon_a(\mathbf{k}) \psi_a^\dagger(\mathbf{k}, \tau) \psi_a(\mathbf{k}, \tau) + \epsilon_b(\mathbf{k}) \psi_b^\dagger(\mathbf{k}, \tau) \psi_b(\mathbf{k}, \tau) \right], \quad (3.8)$$

where the integral is extended over the first Brillouin zone and  $\epsilon_a(\mathbf{k})$  and  $\epsilon_b(\mathbf{k})$  are the anisotropic parabolical dispersions, corresponding to the fermion species a and b, given by

$$\epsilon_a(\mathbf{k}) = \frac{k_x^2}{2m_1} + \frac{k_y^2}{2m_2} - \mu_0 \quad \text{and} \quad \epsilon_b(\mathbf{k}) = \frac{p_x^2}{2m_2} + \frac{p_y^2}{2m_1} - \mu_0, \quad (3.9)$$

where  $\mu_0$  is the chemical potential.

### 3.2 Momentum Conservation in the Spin-Fermion-Model and the Consequence of Umklapp Scattering

In a low-energy theory, our investigated 2D-model is described by the continuum Hamiltonian  $H_\Psi$  for free fermions on the Fermi surface, the effective Hamiltonian  $H_\Phi$  for spin fluctuations and by the interaction Hamiltonian  $H_{\Psi\Phi}$  between both. At the quantum phase transition the control parameter  $r$  in (3.5) is zero, due to  $r = \xi^{-2}$  and the correlation length  $\xi$  diverges. Thus we set  $r = 0$  in the Hamiltonian  $H_\Phi$ . The obtained model Hamiltonian is therefore given by  $H = H_\Psi + H_\Phi + H_{\Psi\Phi}$ . Our further approach is to prove the conservation of momentum and current for this model Hamiltonian. After we introduce a perturbation Hamiltonian for considering umklapp scattering. Because of this perturbation the momentum isn't anymore a conserved quantity. This and the consequences for the current are discussed.

A physical quantity is conserved, if its time derivative vanishes. In quantum mechanics the time derivative is given by Heisenberg equation of motion,  $\dot{A}(t) = i[H, A(t)]_-$ , where  $A(t)$  is an arbitrary operator and its partial time derivative is assumed to be zero. The momentum operator is given by

$$P_j = \int_{\mathbf{k}} k_j \left[ \Psi_a^\dagger(\mathbf{k}, \tau) \Psi_a(\mathbf{k}, \tau) + \Psi_b^\dagger(\mathbf{k}, \tau) \Psi_b(\mathbf{k}, \tau) - \pi_\mu(\mathbf{k}, \tau) \Phi_\mu(-\mathbf{k}, \tau) \right], \quad (3.10)$$

where the spatial direction is indicated by  $j$ , the integral is extended over the first Brillouin zone and the sum over  $\mu$  is implied in the last term. The energy-momentum-tensor, as suggested in [Ili02], is used for the computation. Further the x-component of current operator is given by

$$J_x = - \int_{\mathbf{k}} \left[ \frac{k_x}{m_1} \Psi_a^\dagger(\mathbf{k}, \tau) \Psi_a(\mathbf{k}, \tau) + \frac{k_x}{m_2} \Psi_b^\dagger(\mathbf{k}, \tau) \Psi_b(\mathbf{k}, \tau) \right], \quad (3.11)$$

where the integral is extended over the first Brillouin zone. The y-component of the current operator is yielded by changing the index x to y and interchanging the index a and b of the fermionic field operators. Now, the time derivative of both quantities is computed by using the basic bosonic and fermionic commutator relations. An explicit calculation is represented in the appendix ???. This yields a vanishing time derivative for the momentum,

$$\dot{P}_j = 0, \quad (3.12)$$

and the following expression for the x-component of the current

$$\begin{aligned} \dot{J}_x = \lambda \sum_{\mu} \int_{\mathbf{k}} \int_{\mathbf{q}} \Phi_{\mu}(\mathbf{k} - \mathbf{q}, \tau) & \left[ \left( \frac{q_x}{m_1} - \frac{k_x}{m_2} \right) \Psi_b^\dagger(\mathbf{k}, \tau) \cdot \sigma_{\mu} \cdot \Psi_a(\mathbf{q}, \tau) \right. \\ & \left. + \left( \frac{q_x}{m_2} - \frac{k_x}{m_1} \right) \Psi_a^\dagger(\mathbf{k}, \tau) \cdot \sigma_{\mu} \cdot \Psi_b(\mathbf{q}, \tau) \right]. \end{aligned} \quad (3.13)$$

The y-component of the current is obtained by changing again the index x to y and interchanging the index a and b of the fermionic field operators. The physical interpretation of the obtained results is that momentum is a conserved quantity and current is an unconserved quantity in the spin-fermion-model, described by the Hamiltonian  $H$ . The Hamiltonian is further invariant with respect to time reversal symmetry and a finite overlap is possessed between both quantities. Infinity is obtained for the static electrical conductivity in comparison with the discussion of the previous chapter. A finite conductivity is only obtained by broken translation symmetry. This is equivalent to an unconserved momentum. Therefore, the model Hamiltonian  $H$  is perturbed by umklapp scattering via the Hamiltonian

$$H_{\text{umklapp}} = \sum_{\mu, \mathbf{G}} J_{\mathbf{G}} \int_{\mathbf{k}} \Phi_{\mu}(\mathbf{k}, \tau) \Phi_{\mu}(-\mathbf{k} + \mathbf{G}, \tau), \quad (3.14)$$

where the integral extends over the first Brillouin zone and the sum over  $\mathbf{G}$  included all reciprocal lattice vectors. The quantity  $J_{\mathbf{G}}$  is a coupling constant depending on reciprocal lattice vectors. It is assumed that the coupling constant is decreasing fast to zero in the limit  $|\mathbf{G}| \rightarrow \infty$ . The time derivative of the momentum is given by

$$\dot{P}_j(\tau) = i \sum_{\mathbf{G}} J_{\mathbf{G}} \int_{\mathbf{k}} G_j \Phi_{\mu}(\mathbf{k}, \tau) \Phi_{\mu}(-\mathbf{k} - \mathbf{G}, \tau) \quad (3.15)$$

with respect to the new model Hamiltonian  $H' = H + H_{\text{umklapp}}$ . The time derivative of the current is persisted, since the current and perturbation Hamiltonian depends on fermionic and on bosonic field operators, respectively. The commutator is trivially zero between both field operators. The static electrical conductivity is become finite due to the unconserved momentum. In the next chapter, the static electrical conductivity is explicitly computed using diagrammatic perturbation theory.

## 4 The Static Conductivity in the Spin Fermion Model Pertubated by Umklapp Scattering

In the last chapter the memory-matrix-formalism was introduced, which give us an exact formula to calculate correlation functions. Now this formalism is used to determine the static conductivity of the spin-fermion-model, see chapter ??, pertubated by umklapp-scattering. Firstly the static conductivity of the unpertubated spin-fermion-model is computed to remind and convience us that the conductivity is infinite in the case of unbroken translation symmetry. Afterwards the translational symmetry is broken under consideration of umklapp scattering and the conductivity is calculated for this special case.

### 4.1 Infinite Conductivity in Systems with Unbroken Translation Symmetry

After Drude published his theory about the electrical transport in metals [Dru00] in the beginning of the last century it is well known that a broken translation symmetry is needed to get a finite static conductivity. Because of Neother's theorem [Noe18] it is also well known that a unbroken symmetry always implies a conserved quantity. In the case of translation symmetry this quantity is the momentum. Phenomenas breaking the translation symmetry are for example impurity scattering, electron-electron scattering and umklapp scattering. Let us firstly investigate the standard spin-fermion-model without a translation symmetry breaking pertubation. In chapter ?? it is showed that the unpertubated Hamiltonian conserves the momentum but dosen't conserves the current. This property is utilized in the following calculation of the static conductivity.

In general the static conductivity is given by taking the small frequency limit of the conductivity and the conductivity itself is given by the current-current correlation function (J-J correlation function). This can be proven by assuming a oscillating electrical field and compute the expactaion value of the current via linear response theory, which is done in [Czy17].

$$\sigma_{\text{dc}} = \lim_{\omega \rightarrow 0} \sigma(\omega) = \lim_{\omega \rightarrow 0} \beta \mathcal{C}_{\text{JJ}}(\omega) \quad (4.1)$$

Above in chapter 5 the memory matrix formalism is derivated. Our main goal is to establish equation (5.52) which is an algebraic matrix equation for the correlation

function. Before the computation of  $\mathcal{C}_{JJ}(\omega)$  can be started we have to clarify the set of operators over which we summarized. The sums over  $k$  and  $l$  arise from the projection operator which means we have to discuss the Liouville subspace into the projection operator projects. In general to choice of these operators has to be done for each calculation separately depending on the working model and the quantity of interest. In the investigated case the electrical conductivity and the induction of umklapp scattering at the conductivity is computed. As it is said above the electrical conductivity is proportional to the current operator, why this should be the first operator of our sought set of operators. If an electrical field is applied the electrons accelerate because of the potential difference which increase the momentum of the electrons. Thus the momentum is an inevitable quantity speaking about current and electrical conductivity this should be the second operator. Beside these two operators now more operators are necessary.

The current and momentum have the same signature with respect to time reversal symmetry which simplifies the computation a lot. Considering an invariant Hamiltonian under time reversal symmetry. Then in equation (5.52)  $\Omega_{il}$  vanishes if both operators have the same signature under time reversal symmetry. This assertion is proven in section 5.3.1 in detail. In addition let do the investigation of  $\Sigma_{il}$ . The expectation value is generated with respect to the derivative of an operator at each side. On the right hand side the sum over  $k$  has to be carried out which produces  $|\dot{P}\rangle$  and  $|\dot{J}\rangle$ . The first one is trivially zero, because the momentum is a conserved quantity. The latter has to be investigated under the action of the operator  $Q$ , which projected out off the J-P-subspace.  $Q|\dot{J}\rangle$  describes the coupling on all the other degrees of freedom in the system, which is zero in the considered system. With all these simplifications equation (5.52) yields

$$\begin{pmatrix} \mathcal{C}_{JJ}(\omega) & \mathcal{C}_{JP}(\omega) \\ \mathcal{C}_{PJ}(\omega) & \mathcal{C}_{PP}(\omega) \end{pmatrix} = \frac{i}{\beta} \begin{pmatrix} \omega^{-1} & 0 \\ 0 & \omega^{-1} \end{pmatrix} \cdot \begin{pmatrix} \chi_{JJ}(\omega) & \chi_{JP}(\omega) \\ \chi_{PJ}(\omega) & \chi_{PP}(\omega) \end{pmatrix}. \quad (4.2)$$

The current current correlation function is given by

$$\mathcal{C}_{JJ}(z) = \frac{i}{\beta} \omega^{-1} \chi_{JJ}(\omega = 0) = \frac{i}{\omega} \mathcal{C}_{JJ}(t = 0), \quad (4.3)$$

where relation (5.43) is used. The correlation function at  $t = 0$  is given by the scalar product  $\langle J(0)|J(0) \rangle$ , see equation (5.42). Nothing or nobody bars us from splitting the vector operator  $|J(0)\rangle$  into two pieces, one parallel and one vertical part, which corresponds to the secular and non-secular part of the observable, respectively. Formally this look like

$$|J\rangle = |J_{||}\rangle + |J_{\perp}\rangle. \quad (4.4)$$

In general every observable can be consist a conserved and a non-conserved part, what shouldn't mean that both parts exist in every investigated system. Dissipative processes like fluctuations or initial transient processes for example are included in the non-conserved part. These non-secular effects are visible as noise in the experiment

and the vertical part of the vector is identified with these kinds of processes. Apart from this the secular conserved part of the observable is represented by the parallel part of  $|J\rangle$ . In Drude's theory of conductivity the current is proportional to the momentum in the way that  $j = -\frac{en}{m}p$ . In the spin fermion model, see chapter ??, the momentum is conserved but the current isn't conserved, which means that the conductivity can't be given by Drude's theory at all. Nevertheless because the momentum is conserved the conserved part of the current has to be in the direction of the momentum. In mathematical language this means that the parallel part of the current  $|J_{||}\rangle$  is the projection from  $|J\rangle$  onto  $|P\rangle$ .

$$|J_{||}\rangle = \mathcal{P}|J\rangle = \frac{|P\rangle\langle P|}{\langle P|P\rangle}|J\rangle = \frac{\chi_{PJ}}{\chi_{PP}}|P\rangle \quad (4.5)$$

This gives us the opportunity to write the J-J correlation function into two parts one parallel and one perpendicular correlation function where equation (4.4) is used. The mixed correlation functions are zero by construction, because  $|J_{||}\rangle$  and  $|J_{\perp}\rangle$  are orthogonal and therefore the terms vanish.

$$\mathcal{C}_{JJ}(t=0) = \langle J(0)|J(0)\rangle = \langle J_{||}|J_{||}\rangle + \langle J_{\perp}|J_{\perp}\rangle \quad (4.6)$$

Equation (4.5) is used to express the parallel J-J correlation function as a momentum-momentum correlation function (P-P correlation) formally given by  $\langle P|P\rangle$ .

$$\mathcal{C}_{JJ}(t=0) = \frac{|\chi_{PJ}|^2}{|\chi_{PP}|^2}\mathcal{C}_{PP}(t=0) + \langle J_{\perp}|J_{\perp}\rangle \quad (4.7)$$

Using (5.43) and insert back this expression in equation (4.3) which gives us multiplied with  $\beta$  the conductivity

$$\sigma(z) = \frac{|\chi_{PJ}|^2}{|\chi_{PP}|} \frac{i}{\omega} + \sigma_{\text{reg}}(\omega) \quad (4.8)$$

where the regular conductivity  $\sigma_{\text{reg}}(z) = \frac{i\beta}{\omega} \langle J_{\perp}|J_{\perp}\rangle$  is introduced. The physical meaning of  $\sigma_{\text{reg}}(\omega)$  is directly connected to the vertical component of  $|J\rangle$ . Thus the regular conductivity includes fluctuations and other effects influenced by random forces called noise. Figure 4.1 shows this continuously over all frequencies never disappearing background.

In the whole calculation never a condition on  $\omega$  is made, so the equation for the conductivity is valid for each  $\omega$  in the complex plane. In reality the conductivity isn't depending on a complex frequency, because physical quantities are always real. Therefore we have to set  $\omega = \omega + i\eta$ , where now  $\omega \in \mathbb{R}$  and the limit  $\eta \rightarrow 0$  is implied. Using  $\frac{1}{\omega + i\eta} = \text{P.V.} \frac{1}{\omega} - i\pi\delta(\omega)$  the conductivity is given by

$$\sigma(\omega) = \frac{|\chi_{PJ}|^2}{|\chi_{PP}|} \left( \text{P.V.} \frac{i}{\omega} + \pi\delta(\omega) \right) + \sigma_{\text{reg}}(\omega) \quad (4.9)$$

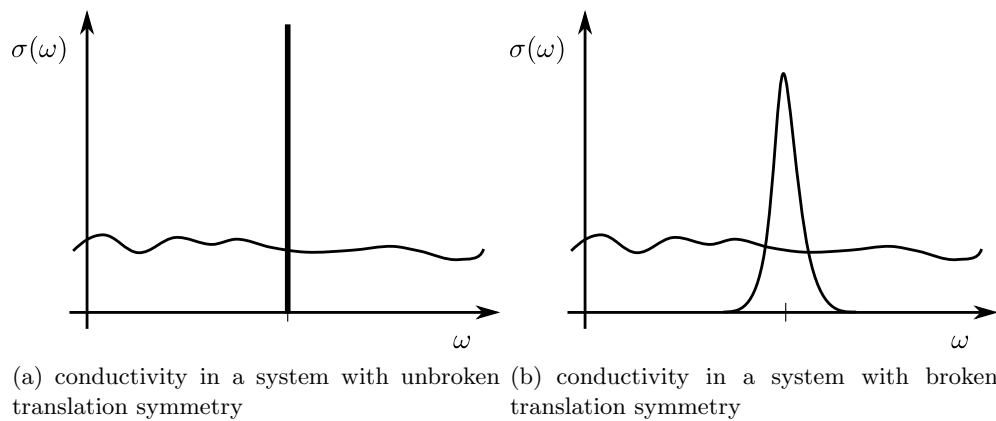

Figure 4.1: caption

where P.V. symbolized that the principal value is taken. Equation (4.9) yields exactly the expected result. For small frequencies the main contribution is generated by the  $\delta$ -distribution, so the conductivity becomes infinite. This is the expected result, because the translation symmetry isn't broken in the investigated system. If voltage is applied on a system with unbroken translational symmetry the electrons accelerate infinite long. There is nothing they can scatter on and therefore nothing to lose momentum. The electrons accelerate more and more and this eventuates in an infinite conductivity. Only in a system with broken translation symmetry it's possible for the electrons to lose momentum by scattering with the lattice or impurities for example. This eventuates in a finite conductivity, thus the amplitude of the  $\delta$ -peak becomes smaller or more precisely finite. The factor in front of the  $\delta$ -distribution is the so called Drude weight. The Drude peak and the effect of breaking translation symmetry is visualized in figure 4.1 too.

## 4.2 Finite Conductivity because of Breaking the Translation Symmetry via Umklapp Scattering

The conservation of momentum connected with an unbroken translation symmetry yields a infinite electrical conductivity, which is computed in the previous section. In the next calculation a system with broken translation symmetry is considered. The assumed symmetry breaking perturbation is umklapp scattering, where the Hamiltonian is given by equation (). In ... it is shown that this perturbation is the reason for an unconserved momentum. Thus the above discussion about the Drude weight and conductivity let us expect that the conductivity is lessened to a finite value. The static electrical conductivity is given by equation (4.1) in general. Again the memory matrix formalism is now used to compute the current-current correlation function given by

link zu umklapp hamiltonian

link zum abschnitt in dem gezeigt wird das P nicht mehr erhalten ist

the formal equation

$$\sum_l \left[ \omega \delta_{il} - \Omega_{il} + i \Sigma_{il}(\omega) \right] \mathcal{C}_{lj}(\omega) = \frac{i}{\beta} \chi_{ij}(0) \quad (4.10)$$

where  $\Omega_{il}$  and  $\Sigma_{il}(\omega)$  are given by

$$\Omega_{il} = i\beta \sum_k (\dot{A}_i | C_k) \chi_{kl}^{-1}(0) \quad \text{and} \quad (4.11)$$

$$\Sigma_{il}(\omega) = i\beta \sum_k (\dot{A}_i | Q \frac{1}{\omega - QLQ} Q | \dot{C}_k) \chi_{kl}^{-1}(0). \quad (4.12)$$

Always the first step is to think about the vector subspace, generated by the vectors of the projection operator. Computing the electrical conductivity the current and the momentum operator are usually the operators of interest. Therefore our decision is made and our subspace is generated by these two operators. What does this choice of operators mean for the quantities  $\Omega_{il}$  and  $\Sigma_{il}(\omega)$ ? Starting with the first one.  $\Omega_{il}$  vanishes if two properties are valid. The first one is, that the considered Hamiltonian has to be invariant with respect to time reversal symmetry. The unpertubated Hamiltonian (...) and the pertubation Hamiltonian (...) occupy this condiction which is trivially to prove. The second property is that both operators labeled with  $A_i$  and  $C_k$  must have the same signature under time reversal symmetry. Both operators can be either J or P, where both have the same signature under time reversal symmetry. Therefore in all cases the quantity  $\Omega_{il}$  is zero. In  $\Sigma_{il}(\omega)$  the expection value is formed with respect of the derivative of vector operators, which are  $|\dot{J}\rangle$  and  $|\dot{P}\rangle$ . In the discussion above a translation invariant system is assumed why the derivative of the momentum vanishes. Now the momentum isn't anymore conserved and therefore the derivative yields a finite value.

vllt noch etwas ausführlicher schreiben

link zum ungestörten Hamiltonian

link zum umklapp Hamiltonian

For further assertions the action of the operator Q has to be investigated on both vector operator.  $Q|\dot{C}_k\rangle$  describes the coupling to all other degrees of freedom which aren't included in the subspace. Firstly remember that umklapp scattering is the considered perturbation. What does this perturbation change in our system? It breaks translation symmetry which yields some finite value for  $\dot{P}$  instead of zero in the unpertubated system. This means the complete unconserved part of the momentum is coupled to the crystal lattice which is clearly a degree of freedom out off the J-P subspace. This is the reason why  $Q|\dot{P}\rangle = |\dot{P}\rangle$ . Further the perturbation doesn't change the quantity  $|\dot{J}\rangle$ . The unconserved current yields from the interaction between the electrons lives on different Fermi surfaces coupeld via spin density waves. This process is included in the J-P subspace and therefore  $Q|\dot{J}\rangle = 0$ . This signifies for the memory function that  $\Sigma_{il}$  doesn't vanish if  $i = P$  and vanish if  $i = J$ .

In summary umklapp scattering yields a non-zero contribution to the memory function  $\Sigma_{il}(\omega)$  and is therefore a correction of the correlation function instead of the unpertubated case where the memory function is zero. Equation (5.52) yields 4 equations in the J-P subspace, which can be written as a matrix equation.

$$\begin{pmatrix} \omega & 0 \\ -i\Sigma_{PJ}(\omega) & \omega - i\Sigma_{PP}(\omega) \end{pmatrix} \cdot \begin{pmatrix} \mathcal{C}_{JJ}(\omega) & \mathcal{C}_{JP}(\omega) \\ \mathcal{C}_{PJ}(\omega) & \mathcal{C}_{PP}(\omega) \end{pmatrix} = \frac{i}{\beta} \begin{pmatrix} \chi_{JJ}(0) & \chi_{JP}(0) \\ \chi_{PJ}(0) & \chi_{PP}(0) \end{pmatrix} \quad (4.13)$$

Before the computation is going on we want to make a short remark. Equation (5.52) is an exact algebraic matrix equation. At the derivation no assumptions are made and up to this point we have also made no assumptions. All the conversion we have done are exact and only depending on the considered model.

The electrical conductivity is given by the J-J correlation function, which has the formal expression

$$\mathcal{C}_{JJ}(\omega) = (J | \frac{i}{\omega - L} | J) \quad (4.14)$$

in frequency space. Equally to the case of conserved momentum nothing bars us to split the current into one parallel and one vertical part, where the parallel part is pointed in the direction of the secular component of  $J$ . The appearing mixed correlation functions vanishes because  $|J_{\parallel}\rangle$  and  $|J_{\perp}\rangle$  are orthogonal. How we have seen in the previous section the background or noise originated by fluctuation and other random processes, which is represented by the correlation function of the vertical component. This term isn't necessary to write it down every time why we drop it. For a discussion in more detail the work of Jung [Jun07] is suggested. However the only important part for us is the parallel component of the correlation function. On the other hand the parallel component of the correlation function is given by the projection of  $J$  onto  $P$ , see equation (4.5). Thus the J-J correlation function is rewritten in a P-P correlation function multiplied with a fraction of susceptibilities.

$$\mathcal{C}_{JJ}(\omega) = (J_{\parallel} | \frac{i}{\omega - L} | J_{\parallel}) = \frac{|\chi_{PJ}|^2}{|\chi_{PP}|^2} \mathcal{C}_{PP}(\omega) \quad (4.15)$$

The P-P correlation function can be readed out of equation (4.13). Therefore the inverse of the memory matrix has to be multiplied from the left hand side. The P-P correlation function is then given by

$$\mathcal{C}_{PP}(\omega) = \frac{i}{\beta} \cdot \frac{i\Sigma_{PJ}(\omega)\chi_{JP}(0)}{\omega(\omega - i\Sigma_{PP}(\omega))} + \frac{i}{\beta} \cdot \frac{\chi_{PP}(0)}{\omega - i\Sigma_{PP}(\omega)} \approx \frac{i}{\beta} \cdot \frac{i\chi_{PP}(0)}{\Sigma_{PP}(\omega)} \quad (4.16)$$

where in the last step the limit of small frequencies is taken. Then on the one hand the first term is neglectable compared to the second one. On the other hand is  $\omega \ll \Sigma_{PP}(\omega)$ . Thus in the second term  $\omega$  is neglectable against  $\Sigma_{PP}(\omega)$ . In summary the static conductivity is given by

$$\sigma_{dc} = \lim_{\omega \rightarrow 0} \beta \mathcal{C}_{JJ}(\omega) = \frac{i}{\beta} \lim_{\omega \rightarrow 0} \frac{|\chi_{PJ}|^2}{\chi_{PP}} \frac{i\beta}{\Sigma_{PP}(\omega)} \quad (4.17)$$

The memory function  $\Sigma_{PP}(\omega)$  is defined in equation (5.55). Because of the considered Hamiltonian only the term included  $\dot{P}$  yields a non-zero contribution. Further the operator  $QLQ$  can be approximated by  $L_0$  the Liouville operator of the unpertubated system. The final expression for the dc-conductivity is given by

$$\sigma_{dc} \approx \frac{i}{\beta} \lim_{\omega \rightarrow 0} |\chi_{PJ}|^2 (\dot{P} | \frac{1}{\omega - L_0} | \dot{P})^{-1} \quad (4.18)$$

Why?

Warum darf QLQ mit  $L_0$  approximiert werden?

In a short conversion the expectation value can be expressed as a time integral over the  $\dot{P}$ - $\dot{P}$  susceptibility. This expression is more usefull for explicite computations, because it allows us using pertubation theory. For the detailed conversion see appendix B. The static electrical conductivity is finally given by

$-\hbar???$

$$\sigma_{\text{dc}} \approx -\hbar \lim_{\omega \rightarrow 0} \frac{\omega |\chi_{\text{JP}}(\omega = 0)|^2}{\int_0^\infty dt e^{i\omega t} \left\langle [\dot{P}(t), \dot{P}(0)] \right\rangle_0}, \quad (4.19)$$

which is used in the computation below. The calculation is splitted into two parts. At first the computation of the denominator is performed, which gives us the temperature dependence of the conductivity. Further the J-P susceptibility has to be calculated. In first order for this quantity is expected no temperature dependence, but we have to convince us from this.

#### 4.2.1 Temperature Dependence of the dc-Conductivity

Our starting point is the integral in the denominator of the last equation above. The index 0 at the expectation value means that it has to be computed with respect to the equilibrium Hamiltonian  $H_1 = H_\Psi + H_\Phi + H_{\Psi\Phi}$ . The considered umklapp scattering is only entered in the time derivative of the momentum. Commonly the sort of this calculation is done in the Matsubara time  $\tau = it$ , see e. g. [BF10] for an introduction or a review.

$$\mathcal{G}_{jj}(z) := \int_0^\infty dt e^{izt} \left\langle [\dot{P}_j(t), \dot{P}_j(0)] \right\rangle_{H_1} = i \int_0^\beta d\tau e^{z\tau} \left\langle \mathcal{T}_\tau \dot{P}_j(\tau) \dot{P}_j(0) \right\rangle_{H_1} \quad (4.20)$$

The norm of the Jacobi determinate is  $-i$  and the upper integral limit changes from infinity to  $\beta$ . Further each time derivative yields an  $i$ . Totally the factor  $i$  is multiplied to the integral. The direction of the momentum is denoted with the index  $j$  and to symbolised clearly that the frequency is an arbitrary number in the complex plane the variable  $z$  is used instead of  $\omega$ . Like it is done every time in pertubation theory the operators are transformed into the Matsubara interaction representation. The transformation's aim is that the expectation value is only taken with respect to the free Hamiltonian  $H_0 = H_\Psi + H_\Phi$  and the interation  $H_{\Psi\Phi}$  is only entered in the time evolution operator  $U(\beta, 0)$ . A series expansion of this one up to the first non-disappearing order yields

$$\mathcal{G}_{jj}(z) = i \int_0^\beta d\tau e^{z\tau} \left\langle \mathcal{T}_\tau \dot{P}_j(\tau) \dot{P}_j(0) \right\rangle_{H_0}^{\text{con}} \quad (4.21)$$

where it has to be remarked that in quantum field pertubation theory only connected diagrams are considered, which is indicated with "con" at the expectation value. At the

numerator all disconnected diagrams can be factorized. These diagrams are exactly the same one as in the denominator, so both cancel each other.

In chapter ?? umklapp scattering is introduced as a perturbation of the spin fermion system described by  $H_1$ . On the basis of this perturbation the momentum isn't anymore conserved, thus the time derivative of the momentum doesn't vanish. The time derivative of an operator is given via the Heisenberg equation of motion, which yields in case of momentum

$$\dot{P}_j(\tau) = \frac{i}{\hbar} \sum_{\mathbf{K}} J_{\mathbf{K}} \int_{\mathbf{k}} K_j \Phi_{\mu}(\mathbf{k}, \tau) \Phi_{\mu}(-\mathbf{k} - \mathbf{K}, \tau) \quad (4.22)$$

where  $j$  indicated the direction of the momentum. The sum over  $\mu$  is implied. Inserting the time derivative of the momentum in  $I_{jj}(z)$  yields

$$\begin{aligned} \mathcal{G}_{jj}(z) = & -\frac{i}{\hbar^2} \sum_{\mathbf{K}_1, \mathbf{K}_2} J_{\mathbf{K}_1} J_{\mathbf{K}_2} \int_0^{\beta} d\tau e^{z\tau} \int_{\mathbf{k}_1} \int_{\mathbf{k}_2} K_{1,j} K_{2,j} \\ & \times \langle \mathcal{T}_{\tau} \Phi_{\mu}(\mathbf{k}_1, \tau) \Phi_{\mu}(-\mathbf{k}_1 - \mathbf{K}_1, \tau) \Phi_{\lambda}(\mathbf{k}_2, 0) \Phi_{\lambda}(-\mathbf{k}_2 - \mathbf{K}_2, 0) \rangle_{H_0} \end{aligned} \quad (4.23)$$

The expectation value is evaluated by using Wick's theorem, where the expectation value is related to the ground state of the system. Therefore all normal products are zero and only the sum survives, where all operators are contracted. The sum yields three possible contraction of the operators, where one of them is a disconnected diagram. The diagram is originated by contracting the operators with the same time argument. This diagram is canceled with the vacuum diagrams like discussed above, because it isn't considered in the following computation. In total Wick's theorem yields two contributing diagrams, where both are equally. The diagram is depicted in figure 4.2 and corresponds to the bubble diagram.

Because the used operators are in momentum space each expectation value of two operators becomes a  $\delta$ -distribution, originated from the commutator relations in momentum space. The  $\delta$ -distributions signify the conservation of momentum. In the investigated case the commutator relations ... have to be used. Then one momentum integral and one sum over reciprocal lattice vectors is performed. The remaining momentum and reciprocal lattice vector is renamed into  $\mathbf{k}$  and  $\mathbf{K}$  respectively. Further one sum over the spacial direction of  $\Phi$  is performed.

$$\begin{aligned} \mathcal{G}_{jj}(z) = & -\frac{2}{\hbar^2} \sum_{\mathbf{K}} |J_{\mathbf{K}}|^2 \int_0^{\beta} d\tau e^{z\tau} \int_{\mathbf{k}} K_j^2 \\ & \times \langle \mathcal{T}_{\tau} \Phi_{\mu}(\mathbf{k}, \tau) \Phi_{\mu}(-\mathbf{k}, 0) \rangle_{H_0} \langle \mathcal{T}_{\tau} \Phi_{\mu}(-\mathbf{k} - \mathbf{K}, \tau) \Phi_{\mu}(\mathbf{k} + \mathbf{K}, 0) \rangle_{H_0}, \end{aligned} \quad (4.24)$$

where  $J_{-\mathbf{K}} = J_{\mathbf{K}}^*$  is used. The asterisk denotes the complex conjugated. Every single expectation value corresponds to the free propagator of spin density waves. The free propagator is defined by  $\mathcal{D}_{\mu}^{(0)}(\mathbf{k}, \tau) := \langle \mathcal{T}_{\tau} \Phi_{\mu}(\mathbf{k}, \tau) \Phi_{\mu}(-\mathbf{k}, 0) \rangle_{H_0}$ . Both are separately

$$\mathcal{G}_{jj}(i\omega_l) = \begin{array}{c} \mathbf{k}, i\omega_n \\ \text{---} \\ \mathbf{k} + \mathbf{K}, i\omega_l - i\omega_n \end{array}$$

Figure 4.2: caption

transformed into Matsubara frequency space via

$$\mathcal{D}_\mu^{(0)}(\mathbf{k}, \tau) = \frac{1}{\beta} \sum_{\omega_n} e^{-i\omega_n \tau} \mathcal{D}_\mu^{(0)}(\mathbf{k}, i\omega_n) \quad (4.25)$$

where the summation runs over all Matsubara frequencies  $\omega_n$ . Because the transformation rotates our investigated function onto the imaginary frequency axis, the complex frequency  $z$  has to be set to  $i\omega_l$ . After transforming the propagators into Matsubara frequency space the imaginary time dependence is solely originated from the exponential functions. This offers us to perform the  $\tau$ -integral easily, where relation

$$\int_0^\beta d\tau e^{-i(\omega_m + \omega_n - \omega_l)\tau} = \beta \delta_{\omega_m + \omega_l - \omega_n} \quad (4.26)$$

is used and then one of the two sums over Matsubara frequencies can be performed as well. After all these steps the integral has the form

$$\mathcal{G}_{jj}(i\omega_l) = -\frac{2}{\hbar^2} \sum_{\mathbf{K}} |\mathbf{J}_{\mathbf{K}}|^2 \int_{\mathbf{k}} K_j^2 \frac{1}{\beta} \sum_{\omega_n} \mathcal{D}_\mu(\mathbf{k}, i\omega_n) \mathcal{D}_\mu(-\mathbf{k} - \mathbf{K}, i\omega_l - i\omega_n) \quad (4.27)$$

In the following the Matsubara sum is evaluated. Therefore we have to check the singularities of both propagators. Regarding equation (6.31), illustrates that the propagator has a discontinuity if the absolute value of the Matsubara frequency is zero. This kind of singularity is called branch cut, because the whole horizontal line at the singularity is forbidden in the complex plane. Branch cuts are the reason why the Matsubara sum isn't so easily transformed into a complex contour integral like it is done usually, if the propagators have simple poles. In the investigated case the propagators have two singularity of this kind, one at  $\omega_n = 0$  and one at  $\omega_n = \omega_l$ , which correspond to  $n = 0$  and  $n = l$ . The strategy to evaluate those Matsubara sums is to separate the singularities from the sum. For reasons of simplizity the momentum argument of the

Figure 4.3: caption

second propagator is abbreviated as  $\mathbf{k}' = -\mathbf{k} - \mathbf{K}$  and the momentum argument is written in both cases as an index until the Matsubara sum is evaluated.

$$\begin{aligned}
S(i\omega_l) &:= \frac{1}{\beta} \sum_{\omega_n} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_n) \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - i\omega_n) \\
\Leftrightarrow S(i\omega_l) &:= \frac{1}{\beta} \mathcal{D}_{\mu, \mathbf{k}}(0) \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l) + \frac{1}{\beta} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_l) \mathcal{D}_{\mu, \mathbf{k}'}(0) \\
&\quad + \frac{1}{\beta} \sum_{\substack{n \neq 0 \\ n \neq l}} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_n) \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - i\omega_n)
\end{aligned} \tag{4.28}$$

Now the remaining sum can be transformed into a complex contour integral. Thereby the contour  $\Gamma$  includes all Matsubara frequencies  $\omega_n$  onto the imaginary axis, beside the two ones splitted off, and is taken counterclockwise. The contour  $\Gamma$  is depicted in figure 4.3. The transformed Matsubara sum is given by

$$I_{MS}(\omega_l) := \frac{1}{\beta} \sum_{\substack{n \neq 0 \\ n \neq l}} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_n) \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - i\omega_n) = \oint_{\Gamma} \frac{dz}{2\pi i} n_B(z) \mathcal{D}_{\mu, \mathbf{k}}(z) \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - z), \tag{4.29}$$

where  $n_B(z)$  is the Bose distribution. Like it is shown in 4.3  $\Gamma$  consists of three single contours which are denoted as  $\Gamma_1$ ,  $\Gamma_2$  and  $\Gamma_3$ . These three contours are expanded to infinity where the contour line is never allow to cross the horizontal line at  $\omega_l$  and 0. The contour  $\Gamma_1$  is taken along the real axis in negative direction and is closed by a semi-circle with infinite radius in the lower complex plane.  $\Gamma_2$  is the contour between both branch cuts. Starting the contour along the real axis in positive direction. At

infinity the contour is going up to the branch cut at  $\omega_n$ , along this axis back to minus infinity and finally back down to the starting point. The last contour  $\Gamma_3$  is going along the  $\omega_n$ -axis in positive direction and is closed by a semi-circle with infinite radius in the upper complex plane. The contour along the real and  $\omega_n$ -axis has to be set infinitesimal beside the axis, which is indicated with the term  $\pm i\eta$ . The sign has to be chosen according to the contour.

Each one of these three contour integrals can be splitted in parts. The contours  $\Gamma_1$  and  $\Gamma_3$  is seperated into the path along the real or  $\omega_l$ -axis, respectively, and the corresponding semi-circle. In both cases the contribution of the semi-circles vanish, because the integrand decreases faster than  $1/z$ . In total  $\Gamma_2$  is seperated into four parts. Two parts are the paths along the real and  $\omega_l$ -axis. The other both paths are the connecting path between them. Equally to the case of the semi-circles these two path vanish. In summary only the paths along the two branch cuts survive.

$$\begin{aligned} I_{MS}(\omega_l) = & \int_{-\infty}^{\infty} \frac{d\epsilon}{2\pi i} \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - \epsilon) \left[ n_B(\epsilon - i\eta) \mathcal{D}_{\mu, \mathbf{k}}(\epsilon - i\eta) - n_B(\epsilon + i\eta) \mathcal{D}_{\mu, \mathbf{k}}(\epsilon + i\eta) \right] \\ & + \int_{-\infty}^{\infty} \frac{d\epsilon}{2\pi i} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_l + \epsilon) \left[ n_B(i\omega_l + \epsilon - i\eta) \mathcal{D}_{\mu, \mathbf{k}'}(\epsilon - i\eta) \right. \\ & \left. - n_B(i\omega_l + \epsilon + i\eta) \mathcal{D}_{\mu, \mathbf{k}'}(\epsilon + i\eta) \right] \end{aligned} \quad (4.30)$$

where the limit  $\eta \rightarrow 0^+$  is implied. Further we used that the propagator  $\mathcal{D}$  is symmetric with respect to the frequency argument. It is easy to prove that  $n_B(z + i\omega_l) = n_B(z)$ , which means that the Bose distribution is invariant with respect to Matsubara frequencies. Thereby is  $z \in \mathbb{C}$  and  $\omega_l = 2\pi l/\beta$  with  $l \in \mathbb{Z}$  is a bosonic Matsubara frequency and therefore  $\exp(i\omega_l) = 1$ . Now we set  $z = \epsilon \pm i\eta$  and investigate the Bose distribution with respect to the limit  $\epsilon \rightarrow 0$ . We expand the exponential function up to the second non-disappearing order, because the singularity of the Bose distribution at  $\epsilon = 0$ .

$$n_B(\epsilon \pm i\eta) \approx \frac{\beta^{-1}}{\epsilon \pm i\eta} = \beta^{-1} \left( \text{P.V.} \frac{1}{\epsilon} \mp i\pi \delta(\epsilon) \right) = n_B(\epsilon) \mp i\pi \beta^{-1} \delta(\epsilon), \quad (4.31)$$

where the last equality is only valid for small frequencies. Going back to equation (4.30). The Bose distributions in both squared brackets become equally, because the Bose distribution is invariant with respect to Matsubara frequencies. Thus the only difference between the terms in the brackets exist in the momentum argument of the propagators. Writing the Bose distribution and the propagators by real and imaginary parts, using that the real parts of  $n_B$  and  $\mathcal{D}$  are symmetric and that the imaginary parts are antisymmetric under changing  $\eta \rightarrow -\eta$ , yield

$$2i \left[ \text{Re}\{n_B(\epsilon + i\eta)\} \text{Im}\{\mathcal{D}_{\mu, \mathbf{k}}(\epsilon + i\eta)\} + \text{Im}\{n_B(\epsilon + i\eta)\} \text{Re}\{\mathcal{D}_{\mu, \mathbf{k}}(\epsilon + i\eta)\} \right] \quad (4.32)$$

nachvollziehen,  
dass die Sym-  
metrieaussage  
stimmt

for the squared brackets in the first line of equation (4.30). An analogical expression is obtained for the squared brackets in the second line changing  $\mathbf{k} \rightarrow \mathbf{k}'$ . Firstly the second term of (4.32) should be investigated. The imaginary part of the Bose distribution is given by equation (4.31), where the  $\delta$ -distribution makes our life easy. Evaluating the obtained relation by integrating with respect to  $\epsilon$  yields

$$-\frac{1}{\beta} \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l) \text{Re}\{\mathcal{D}_{\mu, \mathbf{k}}(0)\} - \frac{1}{\beta} \mathcal{D}_{\mu, \mathbf{k}}(i\omega_l) \text{Re}\{\mathcal{D}_{\mu, \mathbf{k}'}(0)\} \quad (4.33)$$

where the obviously relation  $\text{Re}\{\mathcal{D}_{\mu, \mathbf{k}}(0)\} = \mathcal{D}_{\mu, \mathbf{k}}(0)$  is used. This relation is obviously momentum independent. Comparing this result with the both first terms in (4.28) we see that both expressions are equally beside a global sign and thus both cancel each other. Therefore the only contribution of the Matsubara sum is originated by the first term of the squared brackets in (4.32). The real part of  $n_B(\epsilon + i\eta)$  is  $n_B(\epsilon)$ , see equation (4.31). Further the imaginary part of the propagator is independent of the additional part  $i\eta$ .

$$S(i\omega_l) = \int_{-\infty}^{\infty} \frac{d\epsilon}{\pi} n_B(\epsilon) \left[ \mathcal{D}_{\mu, \mathbf{k}'}(i\omega_l - \epsilon) \text{Im}\{\mathcal{D}_{\mu, \mathbf{k}}(\epsilon)\} + \mathcal{D}_{\mu, \mathbf{k}}(i\omega_l + \epsilon) \text{Im}\{\mathcal{D}_{\mu, \mathbf{k}'}(\epsilon)\} \right] \quad (4.34)$$

Now we are at the point that  $S(i\omega_l)$  can be analytical continued on the real axis. Therefore we have to set  $i\omega_l = \omega + i\eta =: \tilde{\omega}$ , where the limit  $\eta \rightarrow 0^+$  is implied. Regarding equation (6.28) we see that  $\mathcal{D}_{\mu, \mathbf{k}'}(\omega - \epsilon) = \mathcal{D}_{\mu, \mathbf{k}'}^*(\epsilon - \omega)$ , where the asterisk means the complex conjugated.

$$S(\omega) = \int_{-\infty}^{\infty} \frac{d\epsilon}{\pi} n_B(\epsilon) \left[ \mathcal{D}_{\mu, \mathbf{k}'}^*(\epsilon - \omega) \text{Im}\{\mathcal{D}_{\mu, \mathbf{k}}(\epsilon)\} + \mathcal{D}_{\mu, \mathbf{k}}(\epsilon + \omega) \text{Im}\{\mathcal{D}_{\mu, \mathbf{k}'}(\epsilon)\} \right] \quad (4.35)$$

In the first term the frequency argument is shifted from  $\epsilon - \omega \rightarrow \epsilon$ , so that the propagators with the same momentum argument have the same frequency argument. The last step is to take the imaginary part of  $S(\omega)$ . This approach is valid, because the resistivity is defined by the imaginary part of the retarded Green function, which corresponds to (4.27). The only possible complex quantity in (4.27) is the Matsubara sum, defined in (4.28). Thus the imaginary part of the Matsubara sum is given by

$$\text{Im}\{S(\omega)\} = \int_{-\infty}^{\infty} \frac{d\epsilon}{\pi} \left[ n_B(\epsilon) - n_B(\epsilon + \omega) \right] \text{Im}\{\mathcal{D}_{\mu}(-\mathbf{k} - \mathbf{K}, \epsilon)\} \text{Im}\{\mathcal{D}_{\mu}(\mathbf{k}, \epsilon + \omega)\} \quad (4.36)$$

where we used that the imaginary part of the propagator  $\mathcal{D}$  and his complex conjugated one  $\mathcal{D}^*$  are equal beside one minus.  $\text{Im}\{S(\omega)\}$  is inserted in equation (4.27), where

the analytical continuation, which was done for the Matsubara sum, have similarly to do for the Green function.

$$\begin{aligned} G_{jj}^{\text{ret}}(\omega) = & -\frac{2}{\hbar^2} \sum_{\mathbf{K}} |\mathbf{J}_{\mathbf{K}}|^2 \int_{-\infty}^{\infty} \frac{d\epsilon}{\pi} \left[ n_{\text{B}}(\epsilon) - n_{\text{B}}(\epsilon + \omega) \right] \\ & \times \int_{\mathbf{k}} K_j^2 \text{Im}\{\mathcal{D}_{\mu}(-\mathbf{k} - \mathbf{K}, \epsilon)\} \text{Im}\{\mathcal{D}_{\mu}(\mathbf{k}, \epsilon + \omega)\}, \end{aligned} \quad (4.37)$$

The spin density wave propagator is given by equation (6.29), where the second term corresponds to the propagator's imaginary part. Further the limit of small frequencies  $\omega$  is considered. On that account the Bose distribution has to be approximated up to the second order, otherwise the expression would be zero. The expression of the propagators is friendly in the limit of small frequencies thus  $\omega$  can be set to zero. Additional the integrand is an even function with respect to  $\epsilon$ , which is easy to see. Beside the exponential functions the expression is only depending on  $\epsilon^2$ -terms, which are obviously even. The exponential expression is even as well, which is easily shown by factorized the exponential function in the denominator. Therefore the lower limit of the integral is set to zero and is multiplied by two.

$$\begin{aligned} G_{jj}^{\text{ret}}(\omega) = & -\frac{4\gamma^2\beta\omega}{\pi\hbar^2} \sum_{\mathbf{Q}_1, \mathbf{Q}_2} \sum_{\mathbf{K}} |\mathbf{J}_{\mathbf{K}}|^2 \int_0^{\infty} d\epsilon \frac{\epsilon^2 e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \\ & \times \int_{\mathbf{k}} K_j^2 \cdot \frac{1}{(\mathbf{k} + \mathbf{K} - \mathbf{Q}_1)^4 + \gamma^2\epsilon^2} \cdot \frac{1}{(\mathbf{k} + \mathbf{Q}_2)^4 + \gamma^2\epsilon^2} \end{aligned} \quad (4.38)$$

The Green function has to be investigated in different cases to prove the convergence. For large values of the momentum vector the function is clearly convergent because of two reasons. Firstly the function is proportional to  $1/\mathbf{k}^4$  which is a fastly decreasing function with respect to large values of  $\mathbf{k}$ . Secondly the momentum vector is restricted to the first Brillouin zone, so even if there would be a divergence for large  $\mathbf{k}$  the values didn't reach these ones. Nevertheless there can be a divergence if the reciprocal lattice vector component  $K_j$  is large. It's imaginable that  $K_j$  is compensated by the respective component of  $\mathbf{Q}_1$  and thus the denominator is small compared to the numerator. The convergence of the Green function is ensured by the coupling constant  $\mathbf{J}_{\mathbf{K}}$ , which is decreasing fast to zero how longer the coupling distance is. This assumption isn't contradicted to any physical observation.

The situation is slightly different in the case of small values of momentum vectors. Consider the case  $\mathbf{K} - \mathbf{Q}_1 = 0$  and  $\mathbf{Q}_2 = 0$ , which is the most divergent and hence the most dangerous case.

$$G_{jj}^{\text{ret}}(\omega) = -\frac{4\gamma^2\beta\omega}{\pi\hbar^2} |\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^{\infty} d\epsilon \frac{\epsilon^2 e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \int_{\mathbf{k}} \frac{1}{(\mathbf{k}^4 + \gamma^2\epsilon^2)^2} \quad (4.39)$$

It's more convenient for the further computation to transform the variables into dimensionless ones. The transformation instruction for the frequency and momentum

Figure 4.4: caption

is  $x = \beta\epsilon$  and  $\mathbf{y} = \mathbf{k}\sqrt{\beta/\gamma}$ , respectively. The limits of the  $\mathbf{y}$ -integral are changed to  $\pm\pi\sqrt{\beta/\gamma}$ . Further the Jacobi determinate yields in total  $\gamma/\beta^2$ . For reasons of simplicity the constant parameters are combined to  $C$ .

$$G_{jj}^{\text{ret}}(\omega) = C \cdot \beta\omega |\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty dx \frac{x^2 e^x}{(e^x - 1)^2} \int_{\mathbf{y}} \frac{1}{(\mathbf{y}^4 + x^2)^2} \quad (4.40)$$

The following strategy is the transform the two dimensional  $\mathbf{y}$ -integral into plane polar coordinates. The integrand decreases very fast to zero in the limit of large values of  $\mathbf{y}$ , thus the upper boundary of the integral can be set to infinity. Further the angle integral yields the value  $2\pi$ , because the integrand is angular independent.

$$G_{jj}^{\text{ret}}(\omega) = \frac{C}{2\pi} \cdot \beta\omega |\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty dx \frac{x^2 e^x}{(e^x - 1)^2} \int_0^\infty dy \frac{y}{(y^4 + x^2)^2} \quad (4.41)$$

Factorizing  $x^2$  at the fraction and substituting  $z = y^2/x$ . The limits of the integral doesn't changed during this transformation. Besides the new differential is given by  $x dz = 2y dy$ . The resulting  $z$ -integral is exactly solvable and yields

$$\int_0^\infty dz \frac{1}{(z^2 + 1)^2} = \frac{1}{2} \left[ \frac{z}{z^2 + 1} + \arctan(z) \right] \Big|_0^\infty = \frac{\pi}{4} \quad (4.42)$$

Thus only one last integral is left. The integrand is decreasing very fast to zero for large values of  $x$ , so that the upper limit is set to 1. In this integration area the exponential functions can be expanded for small values of  $x$ .

$$G_{jj}^{\text{ret}}(\omega) = \frac{C}{16} \cdot \beta\omega |\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^1 dx \frac{1}{x^3} \quad (4.43)$$

Figure 4.5: caption

In the lower limit the integrand is highly divergent, which is an unphysical solution. Hence the Green function has an infinite value which correspond to an infinite resistance, because of umklapp scattering.

Let us consider our problem with an additional renormalization factor  $r$ . The renormalization factor is connected with the temperature through the relation  $r \sim T^{2/z}$  where  $z$  is some factor which has to be chosen depending on the problem and temperature regime. Our new starting point is equation (4.39) with the difference that we add  $r$  to  $\mathbf{k}^2$ .

Übergang  
schreiben

$$G_{jj}^{\text{ret}}(\omega) = -\frac{4\gamma^2\beta\omega}{\pi\hbar^2}|\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty d\epsilon \frac{\epsilon^2 e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \int_{\mathbf{k}} \frac{1}{((\mathbf{k}^2 + r)^2 + \gamma^2\epsilon^2)^2} \quad (4.44)$$

The computing procedure for the integrals are similar to the previous case. In comparison to the computation above the integral isn't transformed into dimensionless variables at this point. Firstly the momentum integral is transformed into plane polar coordinates via the transformation rule  $\mathbf{k} = (y \cos \phi, y \sin \phi)$ . Again the integrand is angular independent, why the  $\phi$ -integral yields the factor  $2\pi$ . Furthermore the integrand is proportional to  $1/k^4$  and decrease therefore very fast to zero in the limit  $k \rightarrow \infty$ . The upper limit of the  $k$ -integral is set to infinity without any doubt.

Subsequently the factor  $\gamma^2\epsilon^2$  is factorized in the denominator. After that the integral is substituted again, this time with  $z = (r + k^2)/\gamma\epsilon$ . Now it is obvious why the renormalization factor is introduced at this place. Because of the factor  $r$  the lower limit of the integral is now  $r/\gamma\epsilon$  instead of zero, which makes sure that the integral is convergent.

$$G_{jj}^{\text{ret}}(\omega) = -\frac{\beta\omega}{\gamma\pi^2\hbar^2}|\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty d\epsilon \frac{\epsilon^{-1}e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \int_{r/\gamma\epsilon}^\infty dz \frac{1}{(z^2 + 1)^2} \quad (4.45)$$

Figure 4.6: caption

The antiderivative of the  $z$ -integral is given by equation (4.42) and the expression of the Green function is

$$G_{jj}^{\text{ret}}(\omega) = -\frac{\beta\omega}{4\gamma\pi^2\hbar^2} |J_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty d\epsilon \frac{\epsilon^{-1} e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \left[ \pi - \frac{2r/\gamma\epsilon}{1 + (r/\gamma\epsilon)^2} - 2 \tan^{-1} \left( \frac{r}{\gamma\epsilon} \right) \right] \quad (4.46)$$

Now the integral is transformed with  $x = \beta\epsilon$  into dimensionless variables. The integrand is a function which decrease fast to zero for large values of  $x$ , which is depicted in figure 4.4. In good approximation the upper limit can be set to an arbitrary value  $\Lambda$ . So the important contribution is originated in the small values of  $x$  why the expression in squared brackets is expanded up to leading order. The difference of the original and the approximated function are exhibited in figure 4.5. Further the fraction of the exponential functions can be approximated. In total the integrand is independent of the variable  $x$  so the integral yields the factor  $\Lambda$ .

$$G_{jj}^{\text{ret}}(\omega) \approx -\frac{\gamma^2 \Lambda}{3\pi^2 \hbar^2} \cdot |J_{\mathbf{K}}|^2 \cdot K_j^2 \cdot \frac{1}{\beta^2 r^3} \cdot \omega \quad (4.47)$$

The single temperature depending factors are  $\beta$  and  $r$ . The renormalization factor is related to the temperature by relation  $r = T^{2/z}$ . Thus the temperature dependence of the Green function is given by

$$G_{jj}^{\text{ret}}(\omega) \sim \frac{1}{\beta^2 r^3} \sim T^{2-6/z}, \quad (4.48)$$

which means that  $z$  has to be three that the Green function and therefore the resistance is a constant function. For  $z = 6$  the Green function or resistance are proportional to  $T$ . These values are much to large. Normally  $z$  takes on values of  $z = 1$  or  $z = 2$ .

Figure 4.7: caption

Figure 4.5 shows that the agreement of the original and approximated function are only in a small regime valid. If the variable  $x$  increases the value of 0.1 the agreement is miserable, which is clearly depending on the choice of parameters, but in all cases the approximation is only in a small regime good, which should be shown in this comparison. Therefore we want to find another much better approximation for the expression in the squared brackets in equation (4.46).

For a better approximation equation (4.44) is considered again. The treatment of power counting is performed for the momentum integral. The denominator yields  $k^8$  and the numerator yields  $k^2$ , because of the differential  $d^2\mathbf{k}$ . In total this yields the power of  $k^{-6}$ . Beside that the integrand has two possible divergencies  $\gamma\epsilon$  and  $r$ , where both of them are proportional to  $k^2$ . Because of the structure of the integrand we determine the following expression for the Green function.

$$G_{jj}^{\text{ret}}(\omega) = -\frac{4\gamma^2\beta\omega}{\pi\hbar^2}|\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\infty d\epsilon \frac{\epsilon^2 e^{\beta\epsilon}}{(e^{\beta\epsilon} - 1)^2} \frac{1}{(r^2 + \gamma^2\epsilon^2)^{3/2}} \quad (4.49)$$

discussion that  
this is good.  
link to figure

In figure 4.6 the exact solution of the momentum integral and the approximation given by power counting are contrasted. Comparing with our previous approximation this new approximation is much better. Similar to the exact function our approximation is convergent for large values of  $\epsilon$ . Nevertheless let us factorize  $\gamma^2\epsilon^2$  in the denominator and transform into dimensionless variables with  $x = \beta\epsilon$ . Further the dimensionless integral is capped by an arbitrary value  $\Lambda$  again. Then the exponential functions can be expanded with respect to small  $x$ . The resulting integral is exactly solvable.

$$G_{jj}^{\text{ret}}(\omega) = -\frac{4\beta\omega}{\gamma\pi\hbar^2}|\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \int_0^\Lambda dx \frac{1}{\left(\left(\frac{\beta r}{\gamma}\right)^2 + x^2\right)^{\frac{3}{2}}} \sim \frac{\Lambda}{\left(\frac{\beta r}{\gamma}\right)^2 \sqrt{\left(\frac{\beta r}{\gamma}\right)^2 + \Lambda^2}} \quad (4.50)$$

These expression can be expanded for small values of  $\beta r/\gamma\Lambda$ . Now we can insert the temperature depended renormalization factor  $r = T^{2/z}$ . Therefore the Green function is given by

$$G_{jj}^{\text{ret}}(\omega) = -\frac{4\gamma\Lambda^{-1}}{\pi\hbar^2} |\mathbf{J}_{\mathbf{K}}|^2 \cdot K_j^2 \frac{1}{\beta r^2} \cdot \omega \sim T^{1-4/z} \quad (4.51)$$

In comparison to the first investigation of the Green function above, once the term in the squared brackets was expanded in (4.46), this result is a little bit better. Nevertheless the value of  $z$  has to be  $z = 4$  that the Green function and therefor the resistance is proportional  $T^0$  which doesn't match with the normaly values of  $z$ . If we consider  $z = 1$  or  $z = 2$  the resistance would be proportional to  $T^{-3}$  and  $T^{-1}$ , respectively. These results for the temperature dependence are highly divergent.

#### 4.2.2 Computation of the Static Susceptibility

Equation (4.19) contains two possible temperature dependent quantities. Beside the integral, which is calculated in the section above, the static susceptibility is the second one. Our expectation is that the static susceptibility doesn't depend on temperature in leading order, but we have to prove it. With the aid of equation (5.43) the static susceptibility is obviously connected with the Kubo relaxation function (5.10) at  $t = 0$ .

$$\chi_{\text{PJ}}(\omega = 0) = \Phi_{\text{PJ}}(t = 0) = \frac{i}{\hbar} \int_0^\infty dt' \langle [P_j(t'), J_j(0)] \rangle \quad (4.52)$$

In the formula above the limit  $s \rightarrow 0$  is dropped, because we will see that the integral is convergent. The index  $j$  signifies the spatial direction of  $\mathbf{P}$  and  $\mathbf{J}$ . Like always the integral is transformed into Matsubara time  $\tau = it$ , firstly. The Jacobi determinate is  $-i$  and the integral's limits have to be set to 0 and  $\beta$ . In Matsubara interaction representation the normal treatment of perturbation theory is done, where in the case at hand only the leading order of perturbation series is observed.

$$\chi_{\text{PJ}}(\omega = 0) = \frac{1}{\hbar} \int_0^\beta d\tau \langle \mathcal{T}_\tau P_j(\tau) J_j(0) \rangle_0 \quad (4.53)$$

link zu impuls  
im k-raum

link zum strom  
im k-raum

The momentum and current operator are given by equation ... and ..., respectively. Before the operators are inserted into the expectation value let us think about the possible combinations in diagrammatic language. Firstly remember that the numerator and denominator have to be expanded in a series. Doing this completely general the appearing diagrams in the denominator can be factorized in the numerator and thus they cancel each other. Making a long story short only connected diagrams have to be taken into account.

In the investigated order only one pair of bosonic operators, i.e. one propagator, and no interaction between the spin density waves and the electrons are observed.

Figure 4.8: caption

Therefore the bosonic propagator yields always a disconnected diagram. Furthermore pairing electrons of different Fermi surfaces isn't allowed, which means that the expectation value of mixed fermionic operators also yields disconnected diagrams. Thus many diagrams of the investigated ones are disconnected, beside of two. These two bubble diagrams are depicted in figure 4.8.

$$\chi_{PJ}(\omega = 0) = -\frac{1}{\hbar} \int_0^\beta d\tau \int_{\mathbf{k}} \left[ \frac{k_j^2}{m_1} \left\langle \mathcal{T}_\tau \Psi_a^\dagger(\mathbf{k}, \tau) \Psi_a(\mathbf{k}, \tau) \Psi_a^\dagger(\mathbf{k}, 0) \Psi_a(\mathbf{k}, 0) \right\rangle_0 \right. \\ \left. + \frac{k_j^2}{m_2} \left\langle \mathcal{T}_\tau \Psi_b^\dagger(\mathbf{k}, \tau) \Psi_b(\mathbf{k}, \tau) \Psi_b^\dagger(\mathbf{k}, 0) \Psi_b(\mathbf{k}, 0) \right\rangle_0 \right] \quad (4.54)$$

The two expectation value of four fermionic operators can't be solved directly. Wick's theorem offers the opportunity to write these expectation values into a product of expectation values contained only two operators, which are nothing else free propagators. Two contraction are possible for each expectation value in the investigated case above, where one of them vanishes, because the time argument of the contracted operator is the same.

Vielleicht noch etwas zu der delta-Distribution und so schreiben, damit klar ist warum die Operatoren alle beim gleichen Impuls sind.

$$\chi_{PJ}(\omega = 0) = \frac{1}{\hbar} \int_0^\beta d\tau \int_{\mathbf{k}} k_j^2 \left[ \frac{1}{m_1} \mathcal{G}_a^{(0)}(\mathbf{k}, -\tau) \mathcal{G}_a^{(0)}(\mathbf{k}, \tau) + \frac{1}{m_2} \mathcal{G}_b^{(0)}(\mathbf{k}, -\tau) \mathcal{G}_b^{(0)}(\mathbf{k}, \tau) \right] \quad (4.55)$$

where the free fermionic propagator  $\mathcal{G}_\alpha^{(0)}(\mathbf{k}, \tau) = -\langle \mathcal{T}_\tau \Psi_\alpha(\mathbf{k}, \tau) \Psi_\alpha^\dagger(\mathbf{k}, 0) \rangle$  with  $\alpha \in \{a, b\}$  is introduced. The Green functions of electrons are transformed into the Matsubara frequency space, thus the only time dependence is at the exponential functions. The  $\tau$ -integral yields a  $\delta$ -distribution  $\delta(\omega_m - \omega_n)$  and then one sum over the Matsubara frequencies can be performed.

$$\chi_{PJ}(\omega = 0) = \frac{1}{\hbar} \int_{\mathbf{k}} k_j^2 \left[ \frac{1}{m_1} S_a(\omega_n) + \frac{1}{m_2} S_b(\omega_n) \right], \quad (4.56)$$

where the Matsubara sum  $S_\alpha(\omega_n) = \beta^{-1} \sum_{\omega_n} \mathcal{G}_\alpha^{(0)}(\mathbf{k}, \omega_n) \mathcal{G}_\alpha^{(0)}(\mathbf{k}, \omega_n)$  is introduced. The Matsubara theory exhibits that these kinds of sums can be evaluated by rewriting the sum as a contour integral in the complex plane, integrating over the Green function

Figure 4.9: caption

multiplied with the Fermi or Bose distribution caused by the nature of the Green function. This transformation yields

$$S = \frac{1}{\beta} \sum_{\omega_n} \mathcal{G}(\omega_n) = -\frac{1}{2\pi i} \oint_{\Gamma} dz n_F(z) \mathcal{G}(z) \quad (4.57)$$

in the case of a fermionic Green function. Thereby the contour is arbitrary. The only important fact is that all singularities of the Green function has to be excluded of the contour. Only the singularities of the distribution function are included in the contour. The contour  $\Gamma$  is expanded to infinity, where always the singularities of the Green function has to be excluded. This procedure is depicted in figure 4.9. The paths from infinity to the poles and back yield the same contribution beside the sign, why both cancel each other. The contour is therefore deformed to circles around the poles running clockwise and an infinite circle running counterclockwise. The latter is zero, because the Green function is proportional to  $1/z$ . The electronic Green function is given by

$$\mathcal{G}_{\alpha}(\mathbf{k}, \omega_n) = \frac{1}{i\omega_n - \epsilon_{\alpha}(\mathbf{k})}, \quad (4.58)$$

where  $\epsilon_{\alpha}(\mathbf{k})$  is the electron's dispersion relation with respect to the corresponding Fermi surface denoted with a and b (see equation ...), has only simple poles in the complex plane, which means the function is continuous in the whole complex plane. Therefore the well known residuum theorem can be used to evaluate the contour integral.

$$\chi_{\text{PJ}}(\omega = 0) = -\frac{1}{\hbar} \int_{\mathbf{k}} k_j^2 \left[ \frac{1}{m_1} \frac{dn_F(\epsilon_a(\mathbf{k}))}{d\epsilon_a(\mathbf{k})} + \frac{1}{m_2} \frac{dn_F(\epsilon_b(\mathbf{k}))}{d\epsilon_b(\mathbf{k})} \right] \quad (4.59)$$

The derivatives of the distribution function with respect to the dispersion relation appears because the singularity of the Green function at  $z_0 = \epsilon_{\alpha}(\mathbf{k})$  is a singularity of

Link zu den  
Dispersionsre-  
lationen

second order. These two integrals are exactly solvable. Therefore the inetegrals are transformed into polar coordinates. The transformation rule is given by  $(k_x, k_y) = (q\sqrt{2m_{1,2}}\cos(\phi), q\sqrt{2m_{2,1}}\sin(\phi))$ , where two forms are used, because of the different dispersion relation. The  $k_j^2$ -term originates the only angular dependence, which yields  $\cos^2(\phi)$  or  $\sin^2(\phi)$  for the  $x$ - or  $y$ -direction, respectively. Because the limits of the integral are 0 and  $2\pi$  the integral yields the same result in both cases. The upper limit of the  $q$ -integral can be set to infity, because the integrand is decreased very fast to zero for large values of  $q$ .

$$\chi_{PJ}(\omega = 0) = \frac{8\beta\pi}{(2\pi)^2\hbar}\sqrt{m_1m_2}\int_0^\infty dq q^3 \frac{e^{\beta(q^2-\mu)}}{(e^{\beta(q^2-\mu)} + 1)^2} \quad (4.60)$$

The obtained integral can be solved by substituting  $x = \beta(q^2 - \mu)$ . Thereby the first of the two integrals is evaluated with integration by parts In the second integral the integrand is equal to the derivative of the Fermi distributution. All in one the static susceptibility of P and J is given by

$$\chi_{PJ}(\omega = 0) = \frac{\sqrt{m_1m_2}}{\pi\beta\hbar}\ln(e^{\beta\mu} + 1) \quad (4.61)$$

in first order pertubation theory. In the case of  $\mu \gg k_B T$  the argument of the exponential function is very large. Therefore the one is neglectable in the argument of the logarithm and  $\ln(e^{\beta\mu} + 1) \approx \beta\mu$ . In the limit of small temperatures the susceptibility is given by

Heisst es nullte oder erste Ordnung Störungstheorie?

$$\chi_{PJ}(\omega = 0) \rightarrow \frac{\mu\sqrt{m_1m_2}}{\pi\hbar} \quad (T \rightarrow 0) \quad (4.62)$$

The static susceptibility between P and J is temperature independent in the limit of  $\mu \gg k_B T$ , like exactly we have expected.

## 5 Memory-Matrix-Formalism

write a short  
introduction

### 5.1 Motivation

A physicist is always interested in the behaviour and time evolution of the observables of the investigated system. In the middle of the last century many physicists worked on the understanding and mathematical description of one physical process, the Brownian motion. One stochastic theory of these certain physical process is based on the Langevin equation

$$\frac{\partial}{\partial t}A(t) - F_{\text{ex}}(x, t) + \gamma \cdot A(t) = f(t), \quad (5.1)$$

where  $A(t)$  is some arbitrary dynamical observable and  $f(t)$  is a random force like white noise for example. The second term on the left hand side is originated from some external force, which is coupled to the dynamical observable  $A(t)$ . The third term is a damping or friction term. Now let us assume to separate equation (5.1) into two parts. The first part, called  $f_1$ , is a functional of the dynamical observable  $A(t')$ , where  $t_0 \leq t' \leq t$ , so that this part is depending on the history of  $A$ . The second part  $f_2$  should be depending on all other degrees of freedom of the system. Now  $f_1$  is expanded up to the linear order and all terms of higher order and the part  $f_2$  are summarized to the quantity  $F(t)$ . The result is a linearized form of the Langevin equation

$$\frac{\partial}{\partial t}A(t) = \int_{t_0}^t dt' \mathcal{C}(t - t')A(t') + F(t), \quad (5.2)$$

where  $\mathcal{C}$  denotes a correlation function and  $A(t')$  is the deviation of the invariant part of the Hamiltonian. For large time scales the deviation should be vanish, so the time-integral over  $A(t')$  should become zero. For simplification the origin of the time axis is moved to  $t_0$ . In general the Laplace transformation of a function is given by

$$\mathcal{L}\{A(t)\} = A(s) = \int_0^{\infty} dt A(t)e^{-st}. \quad (5.3)$$

Using the Laplace transformation equation (5.2) becomes a algebraic equation of motion. The solution of this equation is given by

$$A(t) = \Xi(t) \cdot A(0) + A'(t) \quad \text{with} \quad A'(t) = \int_0^t dt' \Xi(t-t') F(t'), \quad (5.4)$$

where the function  $\Xi(t)$  is defined by the Laplace transformation of  $\Xi(s) = [s - \mathcal{C}(s)]^{-1}$  and  $\mathcal{C}(s)$  is the Laplace transformation of the correlation function  $\mathcal{C}(t)$ . The main result of equation (5.4) and the motivation for the following introduced memory-matrix-formalism is that the dynamical observable  $A(t)$  can be splitted into two parts.

For the first term on the right hand side the only time-dependence is advected from the correlation function  $\mathcal{C}$ , which is clear considering the definition of  $\Xi$ . This term included the linear contributions of  $A(t)$  by construction. These ones are the mostly important contributions to the time evolution of an observable, because they are secular. In contrast the second term on the right hand side is the convolution between the function  $\Xi(t-t')$  and the function  $F(t')$ . The latter summarize all the non-linear effects, fluctuations and intital transient processes, which are all effects with a small lifetimes in contrast with the secular effects. Therefore these effects shouldn't have large influences on the time evolution of an observable, always large time scales in mind.

Beside the physical interpretation a simple geometrical and mathematical one is very usefull. Let us assume a vector space and the observable should be a vector in this vector space. Then the secular term is a projection on the A-axis and the non-secular term is aquivalent to a vector perpendicular to the A-axis. The memory-matrix-formalism take up this simple interpretation of equation (5.4) and put it in a general and exact form, so that it can be used classically and quantum mechanically.

figure to visualize to splitting of A(t)

## 5.2 Linear Response Theory

Before the derivation of the memory-matrix-formalism can be started some ground work is to do. This section begins with a short reminder of the kubo formula. After that the Kubo relaxation function are introduced and some important relations between her and the retarded susceptibility  $\chi$  are derivated. In the last section finally the splitting of  $\chi$  in a real and an imaginary part is dicussed.

### 5.2.1 Kubo formula

Consider a system in equilibrium represented by the Hamiltonian  $H_0$ . At an arbitrary time  $t'$  a pertubation is switched on, where the pertubation is given by the Hamiltonian  $H_1 = -B \cdot F(t)$ , so that  $H(t) = H_0 + H_1$  is the full Hamiltonian. Thereby  $B$  is an operator by which the pertubation is coupled to the system and  $F(t)$  is a function determining the time evolution of the pertubation. It is assumed that  $F(t) = 0$  for  $t < t'$  so that the system is in thermal equilibrium for all these times.

The physical interest is existed in the question how does an observable  $A$  react on the perturbation switched on at  $t'$ . The answer is given by the thermodynamical expectation value of the operator corresponding to the observable  $A$

$$\langle A \rangle(t) := \text{Tr}\{\rho_S(t)A_S\} = \text{Tr}\{\rho_I(t)A_I\}, \quad (5.5)$$

where the label S and I stand for the Schrödinger and Interaction picture, respectively. The equality of the expectation value in the different representations is shown by the invariance of the trace with respect to cycle permutation. The transformation into the interaction picture is very usefull what we will see after the next step below. In quantum mechanics the time evolution of the density operator is determined by the von Neumann-equation.

$$\frac{d}{dt}\rho_S(t) = -\frac{i}{\hbar}[H(t), \rho_S(t)] \quad \Leftrightarrow \quad \frac{d}{dt}\rho_I(t) = -\frac{i}{\hbar}[H_I, \rho_I(t)] \quad (5.6)$$

The equation is also transformed into the interaction picture, which doesn't change the structure itself but the density operator depends only on the Hamiltonian  $H_I$  now. Integrating and using the boundary condition that the system is in thermal equilibrium at  $t \rightarrow -\infty$  equation (5.6) is resulted in a integral equation.

$$\rho_I(t) = \rho_0 + \frac{i}{\hbar} \int_{-\infty}^t dt' [B_I(t'), \rho_I(t')] F(t') \quad (5.7)$$

Jet it is clear why the interection picture is used. The integrand depends on the Hamiltonian of the pertubation only in linear order which is a perfect starting point for an iterativ solution procedure. Starting with the zeroth order the density operator is trivially the density operator at thermal equilibrium. Inserting the zeroth order on the right hand side of equation (5.7) yields the first order of the density operator, a.s.ø. In linear response theory the iteration is cut off after the first order. Inserting this in equation (5.5) and defining the dynamical susceptibility

$$\chi_{AB}(t-t') = \frac{i}{\hbar} \Theta(t-t') \langle [A_I(t-t'), B_I(0)] \rangle_{H_0} \quad (5.8)$$

yield the Kubo formula

$$\delta \langle A(t) \rangle := \langle A \rangle(t) - \langle A(t) \rangle_{H_0} \approx \int_{-\infty}^{\infty} dt' \chi_{AB}(t-t') F(t'), \quad (5.9)$$

where the label  $H_0$  means that the expactation value is taken with respect to the unpertubated Hamiltonian. We see that the deviation of the observable  $A$  caused by the pertubation is given by the convolution of the dynamical suszeptibilty  $\chi_{AB}(t-t')$  and the time evolution function  $F(t)$ .

### 5.2.2 Kubo relaxation function

After a general equation for the deviation of an observable  $A$  from the equilibrium value is established, we want to investigate a certain kind of perturbation. Let us assume  $F(t) = \Theta(-t) \cdot F \cdot e^{-s\tau}$  the time evolution function of a perturbation, which is switched on adiabatically at  $t = -\infty$  and switched off at  $t$ . Inserting this in equation (5.9) and substituting  $\tau = t - t'$  yield  $\delta \langle A(t) \rangle = \Phi_{AB}(t) \cdot F e^{st}$  with the Kubo relaxation function

$$\Phi_{AB}(t) = \frac{i}{\hbar} \lim_{s \rightarrow 0} \int_t^\infty d\tau \langle [A_I(\tau), B_I(0)] \rangle_0 e^{-s\tau}. \quad (5.10)$$

The arising  $\Theta$ -distributions determine the lower limit of the integral to  $t$ . For a more detailed derivation of the Kubo relaxation function see [Sch08] or [Sch06]. It's not really surprisingly that the Kubo relaxation function and the dynamical susceptibility are closely connected, because the first is derivated out of the latter one. However there exist three very important relations between them both, which are

$$1. \quad \chi_{AB}(t) = -\Theta(t) \frac{d}{dt} \Phi_{AB}(t) \quad (5.11)$$

$$2. \quad \Phi_{AB}(t = 0) = \chi_{AB}(\omega = 0) \quad (5.12)$$

$$3. \quad \Phi_{AB}(\omega) = \frac{1}{i\omega} [\chi_{AB}(\omega) - \chi_{AB}(\omega = 0)]. \quad (5.13)$$

The evidence of these three relations are shown in the appendix A. For the later deviation of the memory-matrix-formalism it's more usefull to write the Kubo relaxation function in another, not so intuitivly form. The goal of the rewriting is to get the expectation value in a commutator-independent form. Doing this two identities are needed, where the first one is

$$\langle [A(t), B(t')] \rangle = \frac{1}{Z} \text{Tr} \{ [\rho, A(t)] B(t') \}, \quad (5.14)$$

where the invariance of the trace with respect to cycling permutation is used. The second one is the Kubo-identity. Thereby the main idea is to use the analogy of the exponential functions to the time evolution<sup>1</sup> of an operator.

$$\begin{aligned} i[\rho, A(t)] &= i[\rho A(t) - A(t)\rho] \\ \Leftrightarrow i[\rho, A(t)] &= i[\rho A(t) - e^{-\beta H} e^{\beta H} A(t) e^{-\beta H}] \end{aligned}$$

---

<sup>1</sup> The time evolution of an operator is given by

$$A_H(t) = e^{iHt/\hbar} A_S(0) e^{-iHt/\hbar}, \quad (5.15)$$

where H and S stands for the Heisenberg and Schrödinger representation, respectively.

$$\begin{aligned}
&\Leftrightarrow i[\rho, A(t)] = -i\rho \int_0^\beta d\lambda \frac{d}{d\lambda} e^{\lambda H} A(t) e^{-\lambda H} \\
&\Leftrightarrow i[\rho, A(t)] = -i\rho \int_0^\beta d\lambda \left[ H e^{i\tilde{\lambda}H/\hbar} A(t) e^{-i\tilde{\lambda}H/\hbar} - e^{i\tilde{\lambda}H/\hbar} A(t) e^{-i\tilde{\lambda}H/\hbar} H \right] \\
&\Leftrightarrow i[\rho, A(t)] = -i\rho \int_0^\beta d\lambda [H, A(t + \tilde{\lambda})] \\
&\Leftrightarrow \frac{i}{\hbar}[\rho, A(t)] = -\rho \int_0^\beta d\lambda \dot{A}(t + \tilde{\lambda}) = -\rho \int_0^\beta d\lambda \dot{A}(t - i\lambda\hbar), \tag{5.16}
\end{aligned}$$

where the derivation of  $A$  with respect to  $t$  is symbolized with the dotted  $A$ . For reasons of lucidity  $\tilde{\lambda} = -i\lambda\hbar$  is introduced through the computation.

Inserting equation (5.14) and (5.16) in the Kubo relaxation function yield the wanted form of the Kubo relaxation function, where on the right hand side of the following computation is integrated by parts, dedicated with PI.

$$\begin{aligned}
\Phi_{AB}(t) &= \frac{i}{\hbar} \lim_{s \rightarrow 0} \int_t^\infty d\tau \langle [A_I(\tau), B_I(0)] \rangle_0 e^{-s\tau} \\
\stackrel{(5.14)}{\Leftrightarrow} \Phi_{AB}(t) &= \frac{i}{\hbar} \lim_{s \rightarrow 0} \int_t^\infty d\tau \frac{1}{Z_0} \text{Tr}\{[\rho_0, A_I(\tau)] B_I(0)\} e^{-s\tau} \\
\stackrel{(5.16)}{\Leftrightarrow} \Phi_{AB}(t) &= - \lim_{s \rightarrow 0} \int_0^\beta d\lambda \int_t^\infty d\tau \langle \dot{A}_I(\tau - i\lambda\hbar) B_I(0) \rangle_0 e^{-s\tau} \\
\stackrel{\text{PI}}{\Leftrightarrow} \Phi_{AB}(t) &= - \lim_{s \rightarrow 0} \int_0^\beta d\lambda \left\langle \left[ A_I(\tau - i\lambda\hbar) e^{-s\tau} \right]_t^\infty + s \int_t^\infty d\tau \dot{A}_I(\tau - i\lambda\hbar) e^{-s\tau} \right\rangle_0 B_I(0) \\
&= \int_0^\beta d\lambda \langle A_I(t - i\lambda\hbar) B_I(0) \rangle_0 = \int_0^\beta d\lambda \langle A_I(t) B_I(i\lambda\hbar) \rangle_0 \tag{5.17}
\end{aligned}$$

Later we will see that the scalar product defining at the memory-matrix-formalism has a similar structure. This provide the opportunity to transform the correlation function out of the language of the memory-matrix-formalism into the Kubo relaxation function, which in turn provide the opportunity to compute the correlation function perturbatively.

### 5.2.3 Kramer-Kronig-relation

All experiences of a human life demonstrating that an incident is always before the reaction of a system, which is called causality. Causality and the condition that the dynamical susceptibility  $\chi_{AB}(t - t')$  is zero for times  $t$  smaller than  $t'$  are equivalent assertions. It's often useful to work in the frequency space which is why we want to investigate what causality means in Fourier space. Consider the Fourier transformation  $\chi_{AB}(\omega)$ , where  $\omega$  is replaced by the complex number  $\omega' + i\omega''$ . For reasons of simplification the origin of the time axis is set to  $t'$ .

$$\chi_{AB}(\omega) = \int_{-\infty}^{\infty} dt e^{i(\omega' + i\omega'')t} \chi_{AB}(t) \quad (5.18)$$

The integral converges if the exponential functions decrease to zero. Causality in time space yields  $t > 0$  and because of that  $e^{-\omega''t}$  decreases only for  $\omega'' > 0$  to zero. In summary causality in Fourier space means that the susceptibility is holomorphic in the upper complex plane ( $\text{Im}\{\omega\} = \omega'' > 0$ ).

Cauchy's integral theorem offers us the opportunity to express the Fourier transformed susceptibility by a contour integral, where the arbitrary contour  $\Gamma$  has to be taken in the upper complex plane or more precisely in the regime where  $\chi_{AB}(\omega)$  is holomorphic.

$$\chi_{AB}(\omega) = \frac{1}{2\pi i} \oint_{\Gamma} d\zeta \frac{\chi_{AB}(\zeta)}{\zeta - \omega} \quad (5.19)$$

Our choice of the contour is some which goes from minus infinity to infinity along the real part axis. Along a semi-circle in the upper half plane the contour is closed. For reason of convergency the contour along the real part axis is moved infinitesimal in the upper half plane, indicated with  $i\eta$ , where  $\eta \rightarrow 0$  is implicated.

The contribution of the semi-circle vanishes because it is assumed that  $\chi_{AB}(\omega)$  decrease very fast for large values of  $\omega$ . Only an integral along the real part axis survives which can be evaluated by formally writing  $\frac{1}{x+i\eta} = \text{P.V.} \frac{1}{x} - i\pi\delta(x)$  where P.V. stands for taking the principal value.

$$\begin{aligned} \chi_{AB}(\omega) &= \frac{1}{2\pi i} \int_{-\infty}^{\infty} d\omega' \frac{\chi_{AB}(\omega')}{\omega' - \omega - i\eta} \\ \Leftrightarrow \chi_{AB}(\omega) &= \frac{1}{2\pi i} \left[ \text{P.V.} \int_{-\infty}^{\infty} d\omega' \frac{\chi_{AB}(\omega')}{\omega' - \omega} + i\pi \int_{-\infty}^{\infty} d\omega' \chi_{AB}(\omega') \delta(\omega' - \omega) \right] \\ \Leftrightarrow \chi_{AB}(\omega) &= -\frac{i}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega' \frac{\text{Re}\{\chi_{AB}(\omega')\}}{\omega' - \omega} + i \text{Im}\{\chi_{AB}(\omega')\} \omega' - \omega \\ \Leftrightarrow \chi_{AB}(\omega) &= \frac{1}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega' \left[ \frac{\text{Im}\{\chi_{AB}(\omega')\}}{\omega' - \omega} - i \frac{\text{Re}\{\chi_{AB}(\omega')\}}{\omega' - \omega} \right] \end{aligned} \quad (5.20)$$

In the second step one right hand side the complex susceptibility is written explicitly by her real and imaginary part. Nothing keep us from doing this on the left side hand too and compare the real and imaginary parts of both sides, respectively.

$$\operatorname{Re}\{\chi_{AB}(\omega)\} = \frac{1}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega' \frac{\operatorname{Im}\{\chi_{AB}(\omega')\}}{\omega' - \omega} \quad (5.21)$$

$$\operatorname{Im}\{\chi_{AB}(\omega)\} = -\frac{1}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega' \frac{\operatorname{Re}\{\chi_{AB}(\omega')\}}{\omega' - \omega} \quad (5.22)$$

These two relations are called Kramers-Kronig-relation. They take the real and imaginary part of the a function, here the susceptibility, in a very usefull relation.

### 5.2.4 Spectral representation

In section 5.2.1 the dynamical susceptibility  $\chi_{AB}$  is introduced by deviated the Kubo-formula (5.9). The evolution of a system, where a pertubation is switched on, is described by this function. Now the processes starting because of the pertubation can be classified into two types. On the one hand in dissipative prozesses and on the other hand in non-dissipative prozesses. In the following dissipative processes are investigated. The dissipative susceptibility of the form

$$\chi''_{AB}(t - t') = \frac{1}{2\hbar} \langle [A(t), B(t')] \rangle \quad (5.23)$$

Why do we choose this typ of  $\chi''(t - t')$

is considered, where the operators A and B are two Hermitian ones. The property

$$(\chi''_{AB}(t - t'))^* = -\chi''_{AB}(t - t') \quad (5.24)$$

is trivially shown because the commutator of two Hermitian operators is anti-Hermitian. The Fourier transformation of  $\chi''_{AB}(t - t')$  is given by equation (5.18). Notice that in the following computation the frequency  $\omega$  isn't splitted into real and imaginary parts. Our calculation is started by multipling equation (5.8) with  $e^{i\omega t}$  and integrating over time  $t$ .

$$\begin{aligned} \chi_{AB}(t) &= \frac{i}{\hbar} \Theta(t) \langle [A(t), B(0)] \rangle = 2i\Theta(t)\chi''_{AB}(t) \\ \Leftrightarrow \chi_{AB}(\omega) &= 2i \int_{-\infty}^{\infty} dt e^{i\omega t} \Theta(t) \chi''_{AB}(t) \\ \Leftrightarrow \chi_{AB}(\omega) &= -\frac{1}{\pi} \lim_{\eta \rightarrow 0} \int_{-\infty}^{\infty} d\omega' \frac{1}{\omega' + i\eta} \int_{-\infty}^{\infty} dt e^{i(\omega - \omega')t} \chi''_{AB}(t) \\ \Leftrightarrow \chi_{AB}(\omega) &= \frac{1}{\pi} \lim_{\eta \rightarrow 0} \int_{-\infty}^{\infty} d\omega' \frac{\chi''_{AB}(\omega')}{\omega' - \omega - i\eta} \end{aligned}$$

$$\begin{aligned}
\Leftrightarrow \chi_{AB}(\omega) &= \frac{1}{\pi} \text{PV} \int_{-\infty}^{\infty} d\omega' \frac{\chi''_{AB}(\omega')}{\omega' - \omega} + i \int_{-\infty}^{\infty} d\omega' \delta(\omega' - \omega) \chi''_{AB}(\omega') \\
\Leftrightarrow \chi_{AB}(\omega) &= \chi'_{AB}(\omega) + i\chi''_{AB}(\omega)
\end{aligned} \tag{5.25}$$

where in the second step the following definition of the  $\Theta$ -function is used.

$$\Theta_{\eta}(t) = i \lim_{\eta \rightarrow 0} \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \frac{e^{-i\omega' t}}{\omega' + i\eta} \tag{5.26}$$

In equation (5.25) we see that the dynamical susceptibility  $\chi_{AB}(\omega)$  is separated into two functions  $\chi'_{AB}(\omega)$  and  $\chi''_{AB}(\omega)$ , where the latter is the dissipative susceptibility defined at the beginning of this section in (5.23). Equation (5.25) is general and for any susceptibility valid. Assuming the dissipative susceptibility is a real number, then this is also valid for  $\chi'_{AB}(\omega)$  and the both functions  $\chi'_{AB}(\omega)$  and  $\chi''_{AB}(\omega)$  are real and imaginary part of  $\chi_{AB}(\omega)$ , respectively.

### 5.3 Deviation of the Memory-Matrix-Formalism

After this short reminder of the linear response theorie and the investigation of the dynamical susceptibility the groundwork for the deviation of the memory-matrix-formalism is done. This chapter started splitting an arbitrary dynamical observable into two parts, a secular and a non-secular one. The systematical evolution of observables is determined by the secular part. Looking at a system after a perturbation is switched off for a long time the secular part depending the evolution. Furthermore all processes with a short lifetime or small magnitudes compared with the linear term in perturbation series are summerized in the non-secular part. This result is the starting point to a simple geometrical interpretation in a vector space, which we want define in the following.

Therefore the mathematical framework in quantum mechanics has to be clear, why a short review based on [Aud05] is given in the following. A  $d$ -dimensional Hilbert-space is mormaly the mathematical working area in quantum mechanics. This vector space is linear, complex and has a defined scalar product. The vectors  $|\phi\rangle$ , usually denoted in the Dirac-notation, are identified with all possible states for a system. Because the man is always interested in observables, linear operators are defined in the Hilbert-space where the eigenvalues of them conform to the observables. Defining the dyad product  $\sum_i |i\rangle\langle i|$  it's not hard to see that any linear operator occupies a dyad decomposition

$$A = \sum_{i,j} |i\rangle\langle i| A |j\rangle\langle j| = \sum_{i,j} A_{ij} |i\rangle\langle j|, \tag{5.27}$$

where  $A_{ij} := \langle i| A |j\rangle$  is a matrix element of the linear operator. The dyad product of an operator is now used to introduce a new vector space of all linear operators

acting on the  $d$ -dimensional Hilbert-space which is called the Liouville-space  $\mathbb{L}$  or also operator space.

The Liouville-space is a linear and complex vector space equally to the Hilbert-space. The difference between both are the vectors or elements living in the space. In the Liouville-space the vectors are linear operators  $A, B, \dots$  which are acting on some Hilbert-space. In other words this means that the dyad decomposition of an vector in the  $d$ -dimensional Hilbert-space is the new vector in the Liouville-space. So some vector in the Liouville-space is notated as

$$|A\rangle := \sum_{ij}^d A_{ij} |i\rangle\langle j|. \quad (5.28)$$

Similiarly to the quantum mechanic the Dirac notation is used with the difference that round brackets are used instead of angle brackets to distinguish both spaces. Out of the definition (5.28) it's clear, that the basis in the Liouville-space is build by the  $d^2$  dyads of the Hilbert-space. The dimension of the Liouville-space is therefore  $d^2$ . Equally to a Hilbert-space there are many other opportunities to choose the basis in the Liouville space  $\mathbb{L}$ , but the definition in (5.28) should be the one we are working with.

In the following the basis of our Liouville space is denoted with  $\{|A_i\rangle\}$  where  $i = 1, 2, 3, \dots, n$  and  $A_i$  is an operator. The corresponding basis of the dual space is given by  $\{\langle A_i|\}$ , similarly to the Hilbert space. The last needed element of our Liouville space is a scalar product which has to fulfill the following three conditions.

$$1. \quad (A_i|A_j) = (A_j|A_i)^* \quad (5.29)$$

$$2. \quad (A_i|B) = c_1(A_i|A_j) + c_2(A_i|A_k),$$

$$\text{where } B = c_1 A_j + c_2 A_k \quad \text{and} \quad c_1, c_2 \in \mathbb{C} \quad (5.30)$$

$$3. \quad (A_i|A_i) \geq 0, \quad \text{where equality is fulfilled if } A_i = 0. \quad (5.31)$$

Beside these the choice of the scalar product is arbitrary. For the moment let us choose

$$(A_i(t)|A_j(t')) = \frac{1}{\beta} \int_0^\beta d\lambda \left\langle A_i^\dagger(t) A_j(t' + i\lambda\hbar) \right\rangle \quad (5.32)$$

as our scalar product, where the normal time evolution of an operator  $A_i(t) = e^{iHt/\hbar} A_i(0) e^{-iHt/\hbar}$  is valid, so that  $A_i(i\lambda\hbar) = e^{-\lambda H} A_i(0) e^{\lambda H}$  can be used. Now we have to proof if the conditions are fulfilled by the choice of our scalar product. Let's get started with the second one because it's easily shown transforming the expectation value into the trace representation and then using the properties of the trace.

Motivation why we choose this kind of a scalar product

$$(A_i(t)|B(t')) = \frac{1}{\beta} \int_0^\beta d\lambda \frac{1}{Z} \text{Tr} \left\{ \rho A_i^\dagger(t) \left[ c_1 A_j(t' + i\lambda\hbar) + c_2 A_k(t' + i\lambda\hbar) \right] \right\}$$

maybe the computation isn't needed here

$$\Leftrightarrow (A_i(t)|B(t')) = c_1(A_i(t)|A_j(t')) + c_2(A_i(t)|A_k(t')) \quad (5.33)$$

The first and third condition can be shown by transforming the scalar product in the spectral representation. Therefore the trace is written explicitly as a sum over all states and the unity operator written as a sum over all projection operators are inserted between both operators  $A_i$  and  $A_j$ .

$$\begin{aligned} (A_i(t)|A_j(t')) &= \frac{1}{\beta \cdot Z} \int_0^\beta d\lambda \sum_{n,m} \langle n| e^{-\beta H} A_i^\dagger(t) |m\rangle \langle m| e^{-\lambda H} A_j(t') e^{\lambda H} |n\rangle \\ \Leftrightarrow (A_i(t)|A_j(t')) &= \frac{1}{\beta \cdot Z} \sum_{n,m} \langle n| A_i^\dagger(t) |m\rangle \langle m| A_j(t') |n\rangle e^{-\beta E_n} \int_0^\beta d\lambda e^{\lambda(E_n - E_m)} \\ \Leftrightarrow (A_i(t)|A_j(t')) &= \frac{1}{\beta \cdot Z} \sum_{n,m} \langle n| A_i^\dagger(t) |m\rangle \langle m| A_j(t') |n\rangle \frac{e^{-\beta E_m} - e^{-\beta E_n}}{E_n - E_m} \end{aligned} \quad (5.34)$$

The complex conjugated of the expectation value is considered in the Liouville space and using  $\langle n| A_j^\dagger(t) |m\rangle^* = \langle m| A_j(t) |n\rangle$  let us find instantly the first condition. Notice that on the right hand side of equation (5.34) only the expectation values are complex quantities. For them the complex conjugation yields

$$\left( \langle n| A_i^\dagger(t) |m\rangle \langle m| A_j(t') |n\rangle \right)^* = \langle n| A_j^\dagger(t') |m\rangle \langle m| A_i(t) |n\rangle \quad (5.35)$$

and inserting back  $(A_i(t)|A_j(t'))^*$  is exactly the same as (5.34). Proofing the third condition it has to be set  $A_j(t') = A_i(t)$  in equation (5.34), which on the right hand side yields

$$\frac{1}{\beta \cdot Z} \sum_{n,m} \left| \langle m| A_i(t) |n\rangle \right|^2 \frac{e^{-\beta E_m} - e^{-\beta E_n}}{E_n - E_m}. \quad (5.36)$$

It's clear that the squared expectation value is always non-negative. The fraction is positive too, which is easily seen by proofing the two cases  $E_n > E_m$  and  $E_n < E_m$ . Therefore the expectation value  $(A_i(t)|A_i(t)) \geq 0$  and equality is only possible if  $A_i = 0$ . All three conditions are well proven and the chosen scalar product is really one's. At this point all the mathematical ground work is done, we know how the vectors look in the Liouville space and we have a well defined scalar product.

The goal of every physical theory is to describe the measurement results. Typically in statistical or quantum mechanics this is done via correlation functions. So our goal is now to find a useable expression for correlation functions in our new Liouville space. The natural starting point describing the time evolution of an operator  $A_i$  is in quantum mechanics the Heisenberg equation of motion

$$\frac{d}{dt} A_i(t) = \dot{A}_i(t) = \frac{i}{\hbar} [H, A_i(t)] = iL A_i(t) \quad (5.37)$$

where the operators are in the Heisenberg representation and the Hermitian Liouville operator  $L = \hbar^{-1}[H, \bullet]$  is introduced, defined by his action on an arbitrary operator. The formal solution of equation (5.37) is given by

$$A_i(t) = e^{itL}A_i(0) = e^{itH/\hbar}A_i(0)e^{-itH/\hbar}. \quad (5.38)$$

In the second step only the definition of the Liouville operator and some algebraic transformations are used. In this notation it is more clearly that the time evolution of an operator is given by the Liouville operator. The same result is obtained in the Liouville space if the Liouville operator is acting on the basis vectors. This isn't really surprisingly because only the dyad product has to be insert in equation (5.37), which results in

Have to convince me that it is really so easy.

$$|\dot{A}_i(t)\rangle = \frac{i}{\hbar}|[H, A_i(t)]\rangle = iL|A_i(t)\rangle \quad (5.39)$$

for the equation of motion in the Liouville space and there formal solution is given by

$$|A_i(t)\rangle = e^{itL}|A_i(0)\rangle. \quad (5.40)$$

Beside the Liouville operator one more operator has to be introduced for the deviation of the correlation function, called the projection operator. Therefore let us define a set of operators  $\{C_i\}$ , where the choice of these operators are differently depending on the investigated system and correlation function. In the later computation of a certain problem the choice of the operators is discussed in more detail. For the moment it's sufficient to know that the set of operators exists. Directly follwing out the definition of the projection operator in quantum mechanics the projection operator in the Liouville space looks like

$$P = \sum_{i,j} |C_i(0)\rangle (C_i(0)|C_j(0)\rangle)^{-1} (C_j(0)|. \quad (5.41)$$

The action of P on some vector  $|A(t)\rangle$  in the Liouville space yields the parallel components to the chosen operators  $C_i$ , which is the projection from  $|A(t)\rangle$  at the vector subspace spanned by  $C_i$ . The corresponding vertical component of  $|A(t)\rangle$  with respect to the operators  $C_i$  is given by  $Q = 1 - P$ , which is the projection out of the vector subspace. Naturally the projection operator is fullfilled the two properties  $P^2 = P$  and  $PQ = QP = 0$  of a projection operator, which follows immediately from the definition of P.

figure of the projector's acting

After the deviation of the time evolution of an operator and the projection operator in Liouville space the correlation function can be defined as

$$C_{ij}(t) = (A_i(t)|A_j(0)) \stackrel{(5.32)}{=} \frac{1}{\beta} \int_0^\beta d\lambda \langle A_i^\dagger(t) A_j(i\lambda\hbar) \rangle, \quad (5.42)$$

where in the last step the definition of the scalar product is only inserted. Comparing equation (5.42) with (5.17) our choice of the correlation function is more clear. The

defined correlation function is proportional to the Kubo relaxation function, which describes the system's reaction on a switched off perturbation, how we learned in section 5.2.2. For  $t = 0$  the correlation function is also proportional to the Fourier transformed susceptibility

$$C_{ij}(t=0) = \frac{1}{\beta} \Phi_{ij}(t=0) = \frac{1}{\beta} \chi_{ij}(\omega=0), \quad (5.43)$$

which directly results from equation (5.12). Equation (5.40) is used to bring the time evolution of the correlation function in more suitable expression

$$C_{ij}(t) = (A_i(0)|A_j(-t)) = (A_i(0)|e^{-itL}|A_j(0)), \quad (5.44)$$

which opens the possibility for using the Laplace transformation. Instead of the definition in equation (5.3) here a form of the Laplace transformation is used where  $s$  is substituted by  $-i\omega$  which is nothing else as a rotation of the definition area by  $\pi/2$ . Multiplying the last equation with  $e^{i\omega t}$  and integrate from zero to infinity with respect to  $t$  yields

$$C_{ij}(\omega) = (A_i|\int_0^\infty dt e^{i(\omega-L)t}|A_j) = (A_i|\frac{i}{\omega-L}|A_j), \quad (5.45)$$

where for reasons of clarity and comprehensibility from now on the argument  $t=0$  isn't anymore written at the basis vectors. Now the relation  $L = LQ + LP$  which follows immediately by using the definition of  $P$  and  $Q$  and the identity  $(X+Y)^{-1} = X^{-1} - X^{-1}Y(X+Y)^{-1}$  is used to simplify the correlation function, where  $X = \omega - LQ$  and  $Y = -LP$ .

$$\begin{aligned} C_{ij}(\omega) &= (A_i|\frac{i}{\omega-LQ-LP}|A_j) \\ \Leftrightarrow C_{ij}(\omega) &= (A_i|\frac{i}{\omega-LQ}|A_j) + (A_i|\frac{1}{\omega-LQ}LP\frac{i}{\omega-L}|A_j) \end{aligned} \quad (5.46)$$

The both terms on the right hand side are considered separately. Let us start with the first one. The fraction can be written as the geometric series assuming  $\frac{LQ}{\omega} < 1$ , which means that the perturbation is small compared to other quantities in the system.

$$\frac{i}{\omega-LQ} = \frac{i}{\omega} \left[ 1 + \frac{LQ}{\omega} + \left(\frac{LQ}{\omega}\right)^2 + \dots \right] \quad (5.47)$$

Each term of the series in the square brackets acting on the operator  $|A_j\rangle$ . Remember this is the operator at time  $t=0$ , which means that no vertical component exists and therefore  $Q|A_j\rangle = 0$ . Every term except the first one contains an operator  $Q$ , so the first term of the correlation function yields

$$(A_i|\frac{i}{\omega-LQ}|A_j) = \frac{i}{\omega} (A_i|A_j) = \frac{i}{\omega} C_{ij}(0). \quad (5.48)$$

write more  
the goal of  
memory ma  
formalism

Ask Jörg if this  
explanation is  
correct

At the second term only the back is considered. Here only the explicit expression of the propagator is inserted, which yields the definition of the Laplace transformed correlation function.

$$P \frac{i}{\omega - L} |A_j\rangle = \sum_{k,l} |C_k\rangle (C_k | C_l)^{-1} (C_l | \frac{i}{\omega - L} |A_j\rangle = \sum_{k,l} |C_k\rangle C_{kl}^{-1}(0) C_{lj}(\omega) \quad (5.49)$$

Inserting back both simplifications the correlation function is get the formal expression

$$C_{ij}(\omega) = \frac{i}{\omega} C_{ij}(0) + \sum_{k,l} (A_i | \frac{1}{\omega - LQ} L | C_k) C_{kl}^{-1}(0) C_{lj}(\omega). \quad (5.50)$$

The form of the resulting correlation function is now much more useable beside the fraction in the expectation value, but this one can be simplified too. Therefore a null  $LQ - LQ$  is added in the nominator.

$$\frac{\omega}{\omega - LQ} = \frac{\omega - LQ + LQ}{\omega - LQ} = 1 + \frac{LQ}{\omega - LQ} \quad (5.51)$$

Multipling with  $\omega$  and inserting the rearrangement of the fraction yields an algebratic equation for the correlation function.

$$\begin{aligned} \omega C_{ij}(\omega) &= i C_{ij}(0) + \sum_{k,l} (A_i | \frac{\omega}{\omega - LQ} L | C_k) C_{kl}^{-1}(0) C_{lj}(\omega) \\ \Leftrightarrow \omega C_{ij}(\omega) &= i C_{ij}(0) + \sum_{k,l} (A_i | 1 + \frac{LQ}{\omega - LQ} L | C_k) C_{kl}^{-1}(0) C_{lj}(\omega) \\ \Leftrightarrow \omega \sum_l \delta_{il} C_{lj}(\omega) &= i \frac{1}{\beta} \chi_{ij}(0) + \sum_l [\Omega_{il} - i \Sigma_{il}(\omega)] C_{lj}(\omega) \\ \Leftrightarrow \sum_l [\omega \delta_{il} - \Omega_{il} + i \Sigma_{il}(\omega)] C_{lj}(\omega) &= i \frac{1}{\beta} \chi_{ij}(0) \end{aligned} \quad (5.52)$$

where equation (5.12) is used and the abbreviations

$$\Omega_{il} := \beta \sum_k (A_i | L | C_k) \chi_{kl}^{-1}(0) \quad \text{and} \quad \Sigma_{il}(\omega) := i \beta \sum_k (A_i | \frac{LQ}{\omega - LQ} L | C_k) \chi_{kl}^{-1}(0) \quad (5.53)$$

are inserted. Equation (5.52) is the wanted algebraic equation for the correlation function. The sums over  $k$  and  $l$  are originated from the utilization of the projection operator. Therefore each sum is summarized over all operators included in the set  $\{C_i\}$  of selected operators. The indicies  $i$  and  $j$  have to be chosen out of this set too, so that equation (5.52) yields  $n^2$  algebraic equations if  $n$  is the number of operators in  $\{C_i\}$ .

write that the founded expression is an exact one

It's useful for later computations to write the even defined abbreviations in another form. For  $\Omega_{il}$  not much work is to do, because we use only equation (5.39), so that

$$\Omega_{il} = i\beta \sum_k (\dot{A}_i | C_k) \chi_{kl}^{-1}(0). \quad (5.54)$$

For the rearrangement of the second abbreviation equation (5.39) is used at the first step too and the fraction is written as the geometric series at the second step. Then in every term the relation  $Q = Q^2$  is inserted, where the proof is an easy finger exercise. After factorizing one  $Q$  to each vector operator the geometric series is written back as a fraction.

$$\begin{aligned} \Sigma_{il}(\omega) &= \frac{i\beta}{\omega} \sum_k (\dot{A}_i | Q \left[ 1 + \frac{LQ}{\omega} + \left( \frac{LQ}{\omega} \right)^2 + \dots \right] | \dot{C}_k) \chi_{kl}^{-1}(0) \\ \Leftrightarrow \Sigma_{il}(\omega) &= \frac{i\beta}{\omega} \sum_k (\dot{A}_i | Q^2 + \frac{Q^2 L Q^2}{\omega} + \frac{Q^2 L Q^2 L Q^2}{\omega^2} + \dots | \dot{C}_k) \chi_{kl}^{-1}(0) \\ \Leftrightarrow \Sigma_{il}(\omega) &= \frac{i\beta}{\omega} \sum_k (\dot{A}_i | Q \left[ 1 + \frac{QLQ}{\omega} + \left( \frac{QLQ}{\omega} \right)^2 + \dots \right] Q | \dot{C}_k) \chi_{kl}^{-1}(0) \\ \Leftrightarrow \Sigma_{il}(\omega) &= i\beta \sum_k (\dot{A}_i | Q \frac{1}{\omega - QLQ} Q | \dot{C}_k) \chi_{kl}^{-1}(0) \end{aligned} \quad (5.55)$$

After all this exhausting mathematical and algebraical conversions the correlation function in the memory matrix formalism is in a useful and workable form. In equation (5.52) the abbreviations can be combined to one function  $M_{il}(\omega) := \Sigma_{il}(\omega) + i\Omega_{il}$ . The symbol  $\Sigma$  is selected in dependence on the quantum mechanical self energy. The function  $M(\omega)$  is called the mass operator in quantum field theory and the memory function in non-equilibrium physics.

Let us discuss the physical meaning of  $\Omega$  and  $\Sigma(\omega)$  in more detail. The quantity  $\Omega$  always vanishes in the case if the considered Hamiltonian occupies time reversal symmetry and if the operators  $A_i$  and  $A_k$  transform with the same signature with respect to time reversal symmetry since then  $(\dot{A}_i | A_k) = 0$ . This assertion is immediately proven extensively in the section below. In this case the memory function is solely given by the function  $\Sigma(\omega)$ . Comparising (5.55) with the definition (5.42) of correlation functions exhibits  $\Sigma(\omega)$  has the structure of a correlation function but  $\Sigma(\omega)$  occupies to differences. On the one hand only  $Q | \dot{A}$  which is perpendicular to  $|A\rangle$  forms the basis vectors of the expectation value. On the other hand only the reduced Liouville operator  $QLQ$  contribute to the expectation value. Let us understand these two object better.

The latter one projects at the part of  $L$ , the full Liouville operator, which causes the intrinsic fluctuations of the operator  $A$ . This means that the function  $\Sigma(\omega)$  describes the dynamic of the operators, which is the interesting part for us. In other words the operators  $QLQ$  describes the internal dynamics of all other degrees of freedom of the system excluded  $A$ , called the "bath". Then  $Q | \dot{A}$  characterizes the coupling to the bath and it's clear, that the dynamic of the bath changes the behaviour of  $A$ .

### 5.3.1 Time Reversal Symmetry

Even above the assertion was postulated that the quantity  $\Omega_{il}$  vanishes if the considered Hamiltonian is symmetric and if the operators  $\dot{A}$  and  $A$  have different signature under time reversal symmetry. In the following section the evidence of this statement is proven. Our starting point is the introduction of the time reversal operator  $T$  via the transformation rule

$$A(t) \rightarrow A'(t) = TA(t)T^{-1} = \epsilon_A A(-t), \quad (5.56)$$

where  $\epsilon_A$  supposes two different values,  $+1$  or  $-1$ . The first one is taken if the physical quantity is something like a position or electrical field and the latter is taken if the physical quantity is a momentum, angular momentum or magnetic field. Now let us firstly investigate the action of  $T$  at the time evolution of an operator.

$$Te^{iHt/\hbar}T^{-1} = e^{-iHt/\hbar} \quad (5.57)$$

Remembering the Hamiltonian is assumed as invariant under time reversal symmetry, so that the only changed quantity is the explicit time argument  $t$ . At next the time derivative of the time evolution of an operator is investigated which yields

$$T \frac{\partial}{\partial t} e^{iHt/\hbar} T^{-1} = \frac{i}{\hbar} T H e^{iHt/\hbar} T^{-1} = \frac{i}{\hbar} T H T^{-1} T e^{iHt/\hbar} T^{-1} = \frac{i}{\hbar} H e^{-iHt/\hbar}, \quad (5.58)$$

where in the second step the unit element  $\mathbb{1} = TT^{-1}$  is inserted. Setting  $t = 0$  and multipling with  $T$  from the right hand side immediatly the commutator relation between the time reversal operator and the Hamiltonian is given by

$$TH = HT \quad \Leftrightarrow \quad [H, T] = 0. \quad (5.59)$$

This is equivalent to the assumption that the Hamiltonian is invariant with respect to time reversal symmetry. This is all we need to know about the time reversal operator to prove the assertion. The expectation value of a Hermitian operator can be easily manipulated with the aim of the time reversal operator  $T$ .

$$\langle B \rangle = \frac{1}{Z} \text{Tr} \left\{ e^{-\beta H} T B T^{-1} \right\} = \left\langle (T B T^{-1})^\dagger \right\rangle \quad (5.60)$$

where the invariance of the trace with respect to cycling permutation and the commutator relation between  $T$  and  $H$  is used in the first step. The anti-unitarity of the time reversal operator and the hermiticity of  $B$  is utilized in the last step. The same stuff is done with the commutator between two Hermitian operators.

$$\left( T [A(t), B(t')] T^{-1} \right)^\dagger = \epsilon_A \epsilon_B \left( [A(-t), B(-t')] \right)^\dagger = -\epsilon_A \epsilon_B [A(-t), B(-t')] \quad (5.61)$$

Finitely coming to the quantity  $\Omega_{il}$  which is proportional to the correlation function  $\langle \dot{A}_i | A_k \rangle$  between a time derivative quantity  $\dot{A}_i$  and the quantity  $A_k$ , as seen in equation

(5.54). Using equation (5.25) yields

$$i\beta(\dot{A}_i|A_k) = i\chi_{\dot{A}_i A_k}(\omega = 0) = i \text{P.V.} \int_{-\infty}^{\infty} \frac{d\omega'}{\pi} \frac{\chi''_{\dot{A}_i A_k}(\omega')}{\omega'} - \lim_{\omega \rightarrow 0} \chi''_{\dot{A}_i A_k}(\omega), \quad (5.62)$$

where the dissipative susceptibility  $\chi''_{\dot{A}_i A_k}(\omega)$  occurs, which differs a little but significant from the dissipative susceptibility  $\chi''_{A_i A_k}(\omega)$  defined in section 5.2.4. To find the relation between both the derivative of (5.23) is formed.

$$\frac{d}{dt} \chi''_{A_i A_k}(t) = \frac{1}{2\hbar} \left\langle \left[ \dot{A}_i(t), A_k(0) \right] \right\rangle = \chi''_{\dot{A}_i A_k}(t) \quad (5.63)$$

Express on both sides the susceptibilities by her Fourier transform yields the wanted relation between both.

$$\chi''_{\dot{A}_i A_k}(\omega) = -i\omega \chi''_{A_i A_k}(\omega) \quad (5.64)$$

Inserting this in (5.65) yields

$$i\beta(\dot{A}_i|A_k) = \text{P.V.} \int_{-\infty}^{\infty} \frac{d\omega'}{\pi} \chi''_{A_i A_k}(\omega') \quad (5.65)$$

where the limit in the second term is taken. This result entails two very important advantages. One the one hand the physical meaning of the quantity  $\Omega_{il}$  becomes clearer, because  $\Omega_{il}$  is directly associated with dissipative processes via  $\chi''_{A_i A_k}(\omega')$ . On the other hand the founded expression establishes the possibility to analyse the behaviour of  $\Omega_{il}$  under time reversal symmetry.

$$\chi''_{A_i A_k}(t - t') = \frac{1}{2\hbar} \left\langle [A_i(t), A_k(t')] \right\rangle \quad (5.66)$$

The expectation value is rewritten using equation (5.60) which establishes the opportunity to use (5.61).

$$\chi''_{A_i A_k}(t - t') = -\epsilon_{A_i} \epsilon_{A_k} \chi''_{A_i A_k}(t' - t), \quad (5.67)$$

where the relation (5.24) is used. The Laplace transformation of this equation yields

$$\chi''_{A_i A_k}(\omega) = -\epsilon_{A_i} \epsilon_{A_k} \chi''_{A_i A_k}(-\omega) = \epsilon_{A_i} \epsilon_{A_k} \chi''_{A_i A_k}(\omega), \quad (5.68)$$

where the antisymmetry of the commutator with respect of interchanging both operators is utilized. Two cases has to be investigated by analyzing the analytical properties of  $\chi''_{A_i A_k}(\omega)$ , which are  $\epsilon_{A_i} = \epsilon_{A_k}$  and  $\epsilon_{A_i} \neq \epsilon_{A_k}$ . The analysis gives us the required properties to compute the integral over the dissipative susceptibility.

**1. case:**  $\epsilon_{A_i} = \epsilon_{A_k}$

This yields  $\chi''_{A_i A_k}(\omega) = \chi''_{A_k A_i}(\omega)$  which means that the dissipative susceptibility is symmetrical under interchanging  $A_i$  and  $A_k$ . Further the dissipative susceptibility is an antisymmetrical function, because  $\chi''_{A_i A_k}(\omega) = -\chi''_{A_i A_k}(-\omega)$ . Consider the complex conjugated of  $\chi''_{A_i A_k}(\omega)$  yields that the dynamical susceptibility is a real number.

$$\left(\chi''_{A_i A_k}(\omega)\right)^* = - \int_{-\infty}^{\infty} dt e^{-i\omega(t-t')} \chi''_{A_i A_k}(t-t') = -\chi_{A_i A_k}(-\omega) = \chi_{A_i A_k}(\omega) \quad (5.69)$$

where equation (5.24) is used.

**2. case:**  $\epsilon_{A_i} \neq \epsilon_{A_k}$

If the signature of  $A_i$  and  $A_k$  is different under time reversal symmetry than the dissipative susceptibility is antisymmetric under the interchange of the both operators so that this yields  $\chi''_{A_i A_k}(\omega) = -\chi''_{A_k A_i}(\omega)$ . For the same reason  $\chi''_{A_i A_k}(\omega)$  is a symmetrical function because  $\chi''_{A_i A_k}(\omega) = \chi''_{A_i A_k}(-\omega)$ . Towards the first case the dissipative susceptibility is an imaginary number which ensures by the complex conjugation likewise.

$$\left(\chi''_{A_i A_k}(\omega)\right)^* = - \int_{-\infty}^{\infty} dt e^{-i\omega(t-t')} \chi''_{A_i A_k}(t-t') = -\chi_{A_i A_k}(-\omega) = -\chi_{A_i A_k}(\omega) \quad (5.70)$$

Back to equation (5.65). We see that the integral vanishes in the first case because the susceptibility is an odd function. This means that  $i\beta(\dot{A}_i|A_k)$  is always zero when the operators  $A_i$  and  $A_k$  have the same signature with respect to time reversal symmetry, assumed the Hamiltonian is invariant under time reversal symmetry. This assertion is equivalent to the one that  $\dot{A}_i$  and  $A_k$  have opposite signature with respect to time reversal symmetry. This is exactly the assertion which we want to prove.

## 6 The Damped Propagator of Spin Density Waves

In the present chapter the propagator of spin density waves should be computed up to the first order in perturbation theory. The main goal of this masterthesis is the determination of the conductivity for the spin fermion model pertubated via umklapp scattering. These processes are determined by spin density waves, see section . . . , why the propagator of them is needed in the calculation of the conductivity.

link to umklapp scattering

Firstly the free spin density wave propagator is computed. Therefore the equation of motion of Green functions is used. An good introduction of this method can be find in every textbook about quantum field theory in many body physics, but the book by Elk and Gasser [EG79] is recommended. Afterwards the damped propagator is calculated using pertubation theory up the first order. Finally the obtained propagator is transformed into the Matsubara frequency space. An easy way to do this is using the Kramer-Kronig relations (??).

### 6.1 The Free Spin Density Wave Propagator

In 5.2 the linear response theory is established and the retarded susceptibility is introduced this way. A susceptibility describes the dynamical behaviour of an operator dependent on an external pertubation. This quantity is close related with the Green function of particles which is called propagator. The only difference is that the operators and the expectation value of the Green function are represented in the Heisenberg picture comparing to the susceptibility, where they are represented with respect to the unpertubated system.

The Green function's equation of motion is easy to get. Therefore the Green function has only to be derivated with respect to the time. The amazing result is that the equation of motion is equally for all typs (retarded, advanced and causal) of Green functions. Only the boundary conditions are different. The obtained equation of motion and the boundary conditions are transformed in Fourier space.

$$\omega \langle \langle A; B \rangle \rangle_{\omega}^j = \langle [A, B]_{\eta} \rangle + \langle \langle [A, H]_{-}; B \rangle \rangle_{\omega}^j \quad (6.1)$$

where  $j$  labels the typ of the Green function (retarded, advanced and causal) and  $\omega$  represented that the Green function is in frequency space. The double angle brackets symbolized the Green function of the operators A and B. This equation is an algebraic equation or more precisely an infinite algebraic equation chain for the green function. On the right hand side in general a new more complicated Green function appears.

For this one exists a new equation chain with a more complicated Green function on the right hand side and so on. In the case of free propagators we are mostly lucky. The appearing Green function isn't really complicated, so that the initial Green function appears after one or two iterative steps. Naturally the same procedure can be done for the Green function in Matsubara time representation. The result is similar to the one above, only the frequency  $\omega$  is replaced with the Matsubara frequency  $i\omega_n$ . The simplicity and advantage of this method instead of other ones is that only commutator relations of the (field) operators are needed. Equation (6.1) is all we need to compute the free propagator of spin density waves.

The dynamic of free spin density waves is described by the Hamiltonian  $H_\Phi$ , introduced in chapter ???. Inserting  $H_\Phi$  and bosonic field operators  $\Phi_\mu$  for A and B in equation (6.1) is the starting point of the following calculation. Therefore the abbreviation  $\langle\langle\Phi_\mu; \Phi_\mu\rangle\rangle_\omega$  is introduced, where the first operator is readed with the momentum argument  $\mathbf{k} + \mathbf{G}$  and in comparison the second operator is readed with the opposite one,  $-\mathbf{k} - \mathbf{G}$ . The time argument is equal in both cases, why it is dropped.

$$\omega\langle\langle\Phi_\mu; \Phi_\mu\rangle\rangle_\omega = \langle[\Phi_\mu(\mathbf{k} + \mathbf{G}), \Phi_\mu(-\mathbf{k} - \mathbf{G})]\rangle + \langle\langle[\Phi_\mu(\mathbf{k} + \mathbf{G}), H_\Phi]; \Phi_\mu\rangle\rangle_\omega \quad (6.2)$$

link zu bosonischen Vertauschungsrelationen

The bosonic commutator relations are given in equation (...). The only non-vanishing commutator relation is that between the bosonic field operator and the corresponding canonical momentum operator. Therefore on the right hand side of (6.2) the inhomogeneity is vanished. Computing the Green function on the same side the Hamiltonian  $H_\Phi$  in equation ... is used. The commutator is given by

link zu  $H_\Phi$

$$\begin{aligned} [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), H_\Phi] &= -\frac{1}{2\epsilon} \sum_{\mathbf{P}} \int_{\mathbf{p}} [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), \pi_\lambda(\mathbf{p} + \mathbf{P}, t) \pi_\lambda(-\mathbf{p} - \mathbf{P}, t)] \\ \Leftrightarrow [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), H_\Phi] &= -\frac{1}{2\epsilon} \sum_{\mathbf{P}} \int_{\mathbf{p}} \left[ \pi_\lambda(\mathbf{p} + \mathbf{P}, t) [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), \pi_\lambda(-\mathbf{p} - \mathbf{P}, t)] \right. \\ &\quad \left. + [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), \pi_\lambda(\mathbf{p} + \mathbf{P}, t)] \pi_\lambda(-\mathbf{p} - \mathbf{P}, t) \right] \\ \Leftrightarrow [\Phi_\mu(\mathbf{k} + \mathbf{G}, t), H_\Phi] &= -\frac{i}{\epsilon} \pi_\mu(\mathbf{k} + \mathbf{G}, t) \end{aligned} \quad (6.3)$$

where the sum over  $\lambda$  is implied at the beginning. Inserting the obtained result of the commutator in equation (6.2) yields the relationship between the initial and the new Green function.

$$\omega\langle\langle\Phi_\mu; \Phi_\mu\rangle\rangle_\omega = -\frac{i}{\epsilon} \langle\langle\pi_\mu; \Phi_\mu\rangle\rangle_\omega \quad (6.4)$$

Equally to the initial Green function an algebraic equation chain is established for the new Green function.

$$\omega\langle\langle\pi_\mu; \Phi_\mu\rangle\rangle_\omega = \langle[\pi_\mu(\mathbf{k} + \mathbf{G}, t), \Phi_\mu(-\mathbf{k} - \mathbf{G}, t)]\rangle + \langle\langle[\pi_\mu(\mathbf{k} + \mathbf{G}, t), H_\Phi]; \Phi_\mu\rangle\rangle_\omega \quad (6.5)$$

Like above the same things are to do. The inhomogeneity is given by the commutator relations .... In comparison to the case above the commutator doesn't vanish this time

link to commutator relations

but it yields  $-i$ . For the Green function on the right hand side the commutator has to be calculated again, which yields  $[\pi_\mu(\mathbf{k} + \mathbf{G}, t), H_\Phi] = i((\mathbf{k} + \mathbf{G})^2 + r_0)\Phi_\mu(\mathbf{k} + \mathbf{G}, t)$ . In total we obtain the relation

$$\omega \langle \langle \pi_\mu; \Phi_\mu \rangle \rangle_\omega = -i + i((\mathbf{k} + \mathbf{G})^2 + r_0) \langle \langle \Phi_\mu; \Phi_\mu \rangle \rangle_\omega. \quad (6.6)$$

Again on the right hand side a new Green function appears. This time the new Green function is well known, it's the initial one. Both equations (6.4) and (6.6) are an equation system, where the Green function  $\langle \langle \pi_\mu; \Phi_\mu \rangle \rangle$  can be eliminated. The easiest way doing this is to multiply equation (6.4) with  $\omega$  and inserting (6.6) in the obtained relation.

$$\mathcal{D}_\mu^{(0)}(\mathbf{k}, \omega) := \langle \langle \Phi_\mu; \Phi_\mu \rangle \rangle_\omega = \sum_{\mathbf{G}} \frac{1}{(\mathbf{k} + \mathbf{G})^2 + r_0 - \xi^{-2}} \quad (6.7)$$

where the inverse squared correlation length  $\xi^{-2} = \epsilon\omega^2$  is introduced. The free propagator exhibits a periodicity with respect to the first Brillouin zone. This condition is used in the calculation of the static conductivity in chapter 4.

say a little bit  
more about that

## 6.2 The Damped Spin Density Wave Propagator

In the previous section the free propagator of spin density waves is computed. Beside the free dynamics the spin fermion model considers an interaction between electrons living on different Fermi surfaces, where the interaction is originated by spin density waves. On that reason the propagation of the spin density waves is damped. The damping should be considered in the propagator via doing perturbation theory.

Because the damping is originated by the interaction between electrons the free electron propagator is also needed in the following calculation. The propagator can be calculated in the same way as the one for free spin density waves. This handwork shouldn't be done here explicitly. The free electron propagator is given by

$$\mathcal{G}_\alpha^{(0)}(\mathbf{k}, \omega) := \langle \langle \Psi_\alpha; \Psi_\alpha^\dagger \rangle \rangle_\omega = \sum_{\mathbf{G}} \frac{1}{\omega - \epsilon_\alpha(\mathbf{k} + \mathbf{G})}, \quad (6.8)$$

where  $\alpha = a, b$  denotes the Fermi surface of the respective electrons. The damped spin density wave propagator is computed using the usually method of perturbation theory in quantum field theory. The full spin density wave propagator is given by

$$\mathcal{D}_\mu(\mathbf{k}, t - t') = -i \langle \mathcal{T}_t U(\infty, -\infty) \Phi_\mu(\mathbf{k} + \mathbf{G}, t) \Phi_\mu(-\mathbf{k} - \mathbf{G}, t') \rangle_0^{\text{con}} \quad (6.9)$$

where  $\mathcal{T}_t$  is the time ordering operator, which orders all contained operators of there right time order. The index 0 denotes that the expectation value is performed with respect to the unpertubated Hamiltonian. The interaction is only incorporated through the time evolution operator  $U$  which is given by

$$U(t, t') = \exp \left( -i \int_{t'}^t dt_1 H_{\text{int}}(t_1) \right). \quad (6.10)$$

The second index "con" at the expectation value denotes that only connected diagrams are considered. In the so called link cluster theorem it is proven that all disconnected diagrams are canceled with the vacuum diagrams, see [Nol09] for it. All these connected diagrams can be simplified a little bit more. There exist diagrams which are contained only diagrams of a lower order in a specific way. It is possible to build these diagrams by multiplying diagrams of lower orders. Therefore a new object  $\Pi$  is introduced, called self energy, which contains all irreducible connected diagrams. The self energy offers the opportunity to write the full Green function as a Dyson equation.

$$\mathcal{D}_\mu = \mathcal{D}_\mu^{(0)} + \mathcal{D}_\mu^{(0)} \Pi_\mu \mathcal{D}_\mu \quad \Rightarrow \quad \mathcal{D}_\mu = \frac{1}{(\mathcal{D}_\mu^{(0)})^{-1} - \Pi_\mu} \quad (6.11)$$

In general the self energy is a complex quantity. Splitting her in a real and imaginary part the real part of its is a correction to the energy and the imaginary part is interpreted as a life time. A finite life time correspondes to a damped particle. The goal of the following calculation is to compute the imaginary part of the self energy. Getting a feeling how the self energy looks in diagrammatic language the full propagator in (6.9) is investigated.

The time evolution operator is expanded up to the second order. The zeroth order yields the free propagator which is calculated in the previous section. Further the first order vanishes. The interaction Hamiltonian  $H_{\Psi\Phi}$  contains one bosonic field operator and therefore combining with the two other bosonic operators this yields an expectation value of three bosonic operators. Wick's theorem says that the expectation value of an odd number of operators is always zero. The reason is that it's impossible to get an term where only contractions are contained. Having an odd number of operators a normal product exist in every term. Taking the equilibrium expectation value of a normal product, it's zero by definition.

The first not vanishing contribution appears at the second order, because the interaction Hamiltonian  $H_{\Psi\Phi}$  contributes twice, thus the number of operators is even in both cases, fermionic and bosonic. In the fermionic case four expectation values appear, where those ones have a little bit different structure like the usually known ones of fermionic operators. The feature of them is that two fermionic operators are connected by a Pauli matrix, which prohibit the use of Wick's theorem or any rearrange of the operators. The expectation values has the special form

$$\left\langle \mathcal{T}_t \Psi_\alpha^\dagger(\mathbf{p}_4, t_2) \cdot \sigma_{\lambda'} \cdot \Psi_\beta(\mathbf{p}_3, t_2) \cdot \Psi_\gamma^\dagger(\mathbf{p}_2, t_1) \cdot \sigma_\lambda \cdot \Psi_\beta(\mathbf{p}_1, t_1) \right\rangle_0, \quad (6.12)$$

where  $\alpha, \beta, \gamma, \delta \in \{a, b\}$  with the property that always two greek letters have to be an "a" and the other two ones a "b". Fierz identity offers the opportunity to eliminate the Pauli matrices. With the aid of Fierz identity a product of the components of two Pauli matrices can be rewritten as a relation of Kronecker symbols.

$$\sum_{\mu=1}^3 \sigma_{ij}^\mu \sigma_{kl}^\mu = 2\delta_{il}\delta_{jk} - \delta_{ij}\delta_{kl} \quad (6.13)$$

Acting Fierz identity the product of field operators and Pauli matrix has to be written in component representation. Then the identity can be use without any doubt and the Kronecker symbols allows us to rewrite the operators without component representation. Doing this we have to rivet on the first term in (6.13), because the order of the operators is rearranged. Therefore the operators has to be commuted with yields a  $\delta$ -distribution with respect to the momentum, see (C.5). The exact calculation is done in the appendix C.

Each obtained expectation values contains two operators of a-electrons<sup>1</sup> and two operators of b-electrons, so that the expectation value can be seperated. One half of these is constructed in a way that both annihilation operators are acting with respect to a-electrons, for example. These kinds of expectation values are surely zero. The other half is "normaly" constructed so that one annihilation and creation operator is acting with respect to a-electrons. The same is surely valid for b-electrons.

Bringing the remained operators in the order that all annihilation operators stands on the left side of the creation operators yields a  $\delta$ -distribution for each commutation, so that in total each term contains two  $\delta$ -distributions. The obtained expectation value is shown in equation (C.6) in the appendix C.

Inserting equation (C.6) for each of the four expectation values two of the four momentum integrals and sums can be performed. The remaining expression for  $\mathcal{D}$  in second order pertubation theory have the form

$$\begin{aligned} \mathcal{D}_\mu^{(2)}(\mathbf{k}, \omega) = & (-i)^3 \lambda^2 \int_{-\infty}^{\infty} dt_1 dt_2 \sum_{\mathbf{P}_1 \mathbf{P}_2} \int_{\mathbf{P}_1} \int_{\mathbf{P}_2} \\ & \times \left\langle \mathcal{T}_t \Phi_{\lambda'}(\tilde{\mathbf{p}}_2 - \tilde{\mathbf{p}}_1, t_2) \Phi_{\lambda}(\tilde{\mathbf{p}}_1 - \tilde{\mathbf{p}}_2, t_1) \Phi_{\mu}(\tilde{\mathbf{k}}, t) \Phi_{\mu}(-\tilde{\mathbf{k}}, t') \right\rangle_0 \\ & \times \left( \left\langle \mathcal{T}_t \Psi_a(\tilde{\mathbf{p}}_2, t_1) \Psi_a^\dagger(\tilde{\mathbf{p}}_2, t_2) \right\rangle_0 \left\langle \mathcal{T}_t \Psi_b(\tilde{\mathbf{p}}_1, t_2) \Psi_b^\dagger(\tilde{\mathbf{p}}_1, t_1) \right\rangle_0 \right. \\ & \left. + \left\langle \mathcal{T}_t \Psi_b(\tilde{\mathbf{p}}_2, t_1) \Psi_b^\dagger(\tilde{\mathbf{p}}_2, t_2) \right\rangle_0 \left\langle \mathcal{T}_t \Psi_a(\tilde{\mathbf{p}}_1, t_2) \Psi_a^\dagger(\tilde{\mathbf{p}}_1, t_1) \right\rangle_0 \right) \end{aligned} \quad (6.14)$$

where the abbreviation  $\tilde{\mathbf{k}} = \mathbf{k} + \mathbf{G}$  and  $\tilde{\mathbf{p}}_i = \mathbf{p}_i + \mathbf{P}_i$  with  $i = 1, 2$  is introduced. In the case of the bosonic expectation value the usually used Wick theorem is utilized. Wick's theorem yields three possible contractions in the corresponding case, where one of these isn't contributed, because it's yielded disconnected diagrams. The remaining two contractions generate four diagrams in total, which are depicted in figure 6.1. These diagrams differentiate only in two points.

On the one hand the acting point of the bosonic lines is changed comparing the first two and last two diagrams. On the other hand the direction of the electronic lines is interchanged between the first two diagrams and in equal measure for the last two diagrams. For example, in the first diagram an a-electron is annihilated and a b-electron is created at  $t_1$ . Comparing the second diagram, where an a-electron is created

<sup>1</sup>a-electrons denotes electrons living on the Fermi surface labeled with a. In comparison b-electrons are electrons on the Fermi surface labeled with b. Both Fermi surfaces are rotated by  $\pi/2$  and shifted by  $(\pm\pi, \pm\pi)$  to each other.

writing this argument in a better way

Figure 6.1: caption

and a b-electron is annihilated at  $t_1$ . All four diagrams are closely connected with each other, because all diagrams can be generated out of one diagram by interchanging the acting point of the bosonic lines or the direction of the fermionic lines. Therefore all four diagrams yield the same contribution, where it is enough to compute one of them and multiply by four.

$$\begin{aligned}
\mathcal{D}_\mu^{(2)}(\mathbf{k}, t - t') &= 4i\lambda^2 \int_{-\infty}^{\infty} dt_1 dt_2 \sum_{\mathbf{P}} \int_{\mathbf{p}} \\
&\times \left\langle \mathcal{T}_t \Phi_\mu(\tilde{\mathbf{k}}, t_2) \Phi_\mu(-\tilde{\mathbf{k}}, t') \right\rangle_0 \left\langle \mathcal{T}_t \Phi_\mu(-\tilde{\mathbf{k}}, t_1) \Phi_\mu(\tilde{\mathbf{k}}, t) \right\rangle_0 \\
&\times \left\langle \mathcal{T}_t \Psi_a(\tilde{\mathbf{p}} - \tilde{\mathbf{k}}, t_1) \Psi_a^\dagger(\tilde{\mathbf{p}} - \tilde{\mathbf{k}}, t_2) \right\rangle_0 \left\langle \mathcal{T}_t \Psi_b(\tilde{\mathbf{p}}, t_2) \Psi_b^\dagger(\tilde{\mathbf{p}}, t_1) \right\rangle_0 \quad (6.15)
\end{aligned}$$

where the momenta  $\mathbf{p}_1$  and  $\mathbf{P}_1$  are relabeled with  $\mathbf{p}$  and  $\mathbf{P}$ , respectively. Accordingly we write  $\tilde{\mathbf{p}}$  instead of  $\tilde{\mathbf{p}}_1$ . In comparison to the Dyson equation (6.11) the fermionic bubble is identified with the self energy  $\Pi_\mu$ , where the bubble diagram surely only represented the zeroth order of the self energy. The self energy in zeroth order is therefore given by

$$\Pi_\mu^{(0)}(\mathbf{k}, \omega) = i \sum_{\mathbf{P}} \int_{|p| \leq p_F} \frac{d^2 \mathbf{p}}{(2\pi)^2} \int_{-\infty}^{\infty} \frac{d\epsilon}{2\pi} \mathcal{G}_a^{(0)}(\mathbf{p} + \frac{\mathbf{k}}{2}, \epsilon + \frac{\omega}{2}) \mathcal{G}_b^{(0)}(\mathbf{p} - \frac{\mathbf{k}}{2}, \epsilon - \frac{\omega}{2}). \quad (6.16)$$

In comparison to equation (6.15) the self energy is represented in frequency space. Further the outer momentum and frequency is shifted by the half of itself, so that both arguments of the fermionic propagators are symmetrically, which is depicted in figure 6.2. How we see in equation (6.8) the free electron propagator contains the

Figure 6.2: caption

dispersion relation  $\epsilon_\alpha(\mathbf{p}+\mathbf{P})$  of the respective electrons. In our considered spin fermion model only electrons near the Fermi surface interact with each other interfered by spin density waves, which means that the momentum and energy transfer is small. Under this condition the dispersion relation can be expanded near the Fermi surface.

$$\begin{aligned}
 \epsilon_a(\mathbf{p} + \mathbf{P} + \frac{\mathbf{k} + \mathbf{G}}{2}) &= \frac{(p_x + P_x + \frac{k_x + G_x}{2})^2}{2m_1} + \frac{(p_y + P_y + \frac{k_y + G_y}{2})^2}{2m_2} \\
 \Leftrightarrow \epsilon_a(\mathbf{p} + \mathbf{P} + \frac{\mathbf{k} + \mathbf{G}}{2}) &= \frac{(p_x + P_x)^2}{2m_1} + \frac{1}{2} \frac{p_x + P_x}{m_1} (k_x + G_x) + \frac{(k_x + G_x)^2}{8m_1} \\
 &\quad + \frac{(p_y + P_y)^2}{2m_2} + \frac{1}{2} \frac{p_y + P_y}{m_2} (k_y + G_y) + \frac{(k_y + G_y)^2}{8m_2} \\
 \Leftrightarrow \epsilon_a(\mathbf{p} + \mathbf{P} + \frac{\mathbf{k} + \mathbf{G}}{2}) &\approx \xi_a + \frac{1}{2} \mathbf{v}_{a,F}(\mathbf{k} + \mathbf{G}) + \mu
 \end{aligned} \tag{6.17}$$

where the quadratic term with respect to  $\mathbf{k}$  is neglectable, because the bosonic transferred momentum is assumed as small. Further the velocity  $\mathbf{v}_a$  of the a-electrons is introduced, where the electron velocity can be approximated with the Fermi velocity of the corresponding Fermi surface, because only electrons near the Fermi surface are considered. Besides the dispersion relation  $\xi_a$  of the a-electrons is used, which is given by .... The same procedure is done for the b-electrons. Finally the normalized momentum vector  $\mathbf{n} = \frac{\mathbf{p}+\mathbf{P}}{|\mathbf{p}+\mathbf{P}|}$  is introduced. The Fermi velocity of the a-electrons is then given by  $\mathbf{v}_{a,F} = v_{a,F}\mathbf{n}$  for example. The scalar product between the normalized momentum vector  $\mathbf{n}$  and the bosonic spin density wave vector  $\mathbf{k} + \mathbf{G}$  is rewritten as his magnitude multiplied with  $\cos(\vartheta)$ , where  $\vartheta$  is the angle between both.

In the investigated spin fermion model the electrons on different Fermi surfaces only interact on so called hot spots like we have it introduced in chapter ???. The energy and the magnitudes of the Fermi velocities are equal on the hot spots.

$$\xi := \xi_a = \xi_b \quad v_F := v_{a,F} = v_{b,F} \tag{6.18}$$

Consider that the direction of the velocities haven't been equal, otherwise the angle  $\vartheta$  is 0 or  $\pi$  and the imaginary part of  $\Pi_\mu$  is zero. Using these assumptions the self

link zur dispersion im spin fermion model

energy is given by

$$\begin{aligned}\Pi_{\mu}^{(0)}(\mathbf{k}, \omega) &= i\nu_F \int_0^{\pi} d\vartheta \int_{\xi \leq \xi_F} d\xi \int_{-\infty}^{\infty} \frac{d\epsilon}{2\pi} \\ &\times \frac{1}{\epsilon + \frac{\omega}{2} - \xi - \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) + i\eta \operatorname{sign}(\epsilon + \frac{\omega}{2})} \\ &\times \frac{1}{\epsilon - \frac{\omega}{2} - \xi + \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) + i\eta \operatorname{sign}(\epsilon - \frac{\omega}{2})},\end{aligned}\quad (6.19)$$

where the two dimensional momentum integral is firstly transformed in plane polar coordinates and then the  $k$ -integral is transformed into an energy integral over the density of states. Because only electrons near the Fermi surface are considered the density of states can be approximated with the constant one  $\nu_F := \nu(\xi_F)$  at the Fermi surface. The energy integral is certainly limited by the Fermi energy  $\xi_F$ .

The further investigation is been starting with the computation of the frequency integral. Therefore the integral over  $\epsilon$  is transformed into a complex contour integral, where the contour  $\Gamma$  is chosen in two different ways. In both case the contour starts along the real axis. According to the singularities of the integrand the countour is closed in the upper or lower half plane via a semicircle with radius infinity. In both cases the contribution of the semicircle is zero because the integrand is proportional to  $1/\epsilon$ . The non-contributing of the semicircle ensures the equality between the integral along the real axis and the complex contour integral. The investigated integrand occupies two singularities at

$$\epsilon_1 := \xi - \frac{1}{2}(\omega - v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)) \quad \text{and} \quad \epsilon_2 := \xi + \frac{1}{2}(\omega - v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)), \quad (6.20)$$

where both singularities are of first order which allows using Cauchy's integral formula. According to the signum function in both denominators the poles are located in the upper or lower plane. So in total there are four different possible constitutions. On the one hand both singularities can be located in the lower or upper complex plane, which yield in both cases zero. On the other hand one pole can be in the upper plane and the other one can be in the lower plane, or vice versa. Equally both constitutions yields the same contribution.

**1. case:**  $\operatorname{sign}(\epsilon + \frac{\omega}{2}) = \operatorname{sign}(\epsilon - \frac{\omega}{2})$

Both singularities are located in the upper or in the lower complex half plane. The contour is therefore closed in the upper or lower plane, respectively, so that both poles are enclosed. In the first case the winding number is 1, because the pole is enclosed counterclockwise. Accordingly the winding number is  $-1$  in the second case.

$$\begin{aligned}I_{\omega}^e &:= i \oint_{\Gamma} \frac{d\omega}{2\pi i} \frac{1}{\omega - \omega_1 \mp i\eta} \cdot \frac{1}{\omega - \omega_2 \mp i\eta} \\ \Leftrightarrow I_{\omega}^e &= \pm i \left[ \frac{1}{\omega_2 - \omega_1} + \frac{1}{\omega_1 - \omega_2} \right] = 0,\end{aligned}\quad (6.21)$$

where the index "e" stands for even and should mean that both poles are located at the same half planes.

**2. case:**  $\text{sign}(\epsilon + \frac{\omega}{2}) \neq \text{sign}(\epsilon - \frac{\omega}{2})$

The singularities are located in different complex half planes, one in the upper and accordingly the other in the lower half plane. In both cases it's arbitrary how the contour is closed. It's only important that one of the two poles is located inside the contour. In the following computation the contour is closed in the upper half plane, so the winding number is always 1.

$$\begin{aligned} I_{\omega}^{\text{o}} &:= i \oint_{\Gamma} \frac{d\omega}{2\pi i} \frac{1}{\omega - \omega_1 \mp i\eta} \cdot \frac{1}{\omega - \omega_2 \pm i\eta} \\ &\Leftrightarrow I_{\omega}^{\text{o}} = \frac{\pm i}{\omega_2 - \omega_1 \pm i\eta} \end{aligned} \quad (6.22)$$

where the index "o" stands accordingly for odd and should mean that both poles are located in different half planes.

Inserting both singularities  $\omega_1$  and  $\omega_2$  causes that the integrand is independent with respect to the energy  $\xi$ . The frequency depending signum functions in (6.19) is equivalent to the signum functions  $\text{sign}(\xi \pm \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta))$  in energy representation. The energy  $\xi$  is neglectable because the integrand is independent of  $\xi$ . Further the constant factors are also neglectable because they are always positive. The case of sign in the integrand depends therefore only on the sign of  $|\mathbf{k} + \mathbf{G}|\cos(\vartheta)$ . Finally the integrals limits has to be set to  $\pm \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)$ . This follows directly from the location of the poles. For example if  $\omega_1$  is in the lower and  $\omega_2$  is in the upper half plane than  $\epsilon + \frac{\omega}{2} > 0$  and  $\epsilon - \frac{\omega}{2} < 0$ , respectively. Transforming both into energy representation the corresponding expressions are  $\xi - \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) < 0$  and  $\xi + \frac{1}{2}v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) > 0$ , which yields directly the definition interval of  $\xi$ . Therefore we obtained

$$\Pi_{\mu}^{(0)}(\mathbf{k}, \omega) = i\nu_F \int_0^{\pi} d\vartheta \int_{-\xi_0}^{\xi_0} d\xi \frac{i \text{sign}(|\mathbf{k} + \mathbf{G}|\cos(\vartheta))}{\omega - v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) + i\eta \text{sign}(|\mathbf{k} + \mathbf{G}|\cos(\vartheta))} \quad (6.23)$$

for the self energy, where the abbreviation  $\xi_0 = v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)/2$  is introduced. The integration over  $\xi$  yields the factor  $v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)$ . Subsequently the signum function is reexpressed in frequency representation which corresponds to  $\text{sign}(\omega)$ .

Like it is shown above the damping of the spin density wave occurs of the imaginary part of the self energy, which is the reason why we take the imaginary part of the above expression in the further computation. The imaginary part of the self energy is given by

$$\text{Im}\{\Pi_{\mu}^{(0)}(\mathbf{k}, \omega)\} = \nu_F \pi \int_0^{\pi} d\vartheta v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta) \delta(\omega - v_F|\mathbf{k} + \mathbf{G}|\cos(\vartheta)), \quad (6.24)$$

where the formula  $\frac{1}{x \pm i\eta} = \text{P.V.} \frac{1}{x} \mp i\pi\delta(x)$  is used. To perform the last remaining integral over  $\vartheta$  the  $\delta$ -distribution has to be rewritten. The argument is a  $\vartheta$  depending function with in general infinite zeros. But in the integrating area, between 0 and  $\pi$ , the cosine only have one zero. The formula

$$\delta(g(x)) = \sum_{i=1} \frac{\delta(x - x_{0,i})}{|g'(x_{0,i})|} \quad (6.25)$$

states how a  $\delta$ -distribution with a functional argument can be written as a sum over  $\delta$ -distributions with zeros of  $g(x)$  as arguments. The prime denotes the derivative with respect to  $x$  which has to be evaluated at the corresponding zero  $x_{0,i}$ . The argument of the  $\delta$ -distribution in (6.24) has a single zero at  $\vartheta_0 = \cos^{-1}(\omega/(v_F|\mathbf{k} + \mathbf{G}|))$ . Thereby the  $\delta$ -distribution is rewritten as

$$\begin{aligned} \delta(\omega - v_F|\mathbf{k} + \mathbf{G}| \cos(\vartheta)) &= \left( v_F|\mathbf{k} + \mathbf{G}| \cdot |\sin(\vartheta_0)| \right)^{-1} \delta(\vartheta - \vartheta_0) \\ \Rightarrow \delta(\omega - v_F|\mathbf{k} + \mathbf{G}| \cos(\vartheta)) &\approx \left( v_F|\mathbf{k} + \mathbf{G}| \right)^{-1} \delta(\vartheta - \vartheta_0) \end{aligned} \quad (6.26)$$

where in the second line the limit of small frequencies  $\omega$  is performed. This is valid because of our investigated low energy theory. In other words the interaction is assumed as small and thereby the frequency and momentum transfer is small too. Now the integration over  $\vartheta$  can be performed easily. The imaginary part of the self energy is given by

$$\text{Im}\left\{ \Pi_{\mu}^{(0)}(\mathbf{k}, \omega) \right\} = \frac{\nu_F \pi}{v_F|\mathbf{k} + \mathbf{G}|} \cdot \omega = \gamma\omega \quad (6.27)$$

where in the last step the damping constant  $\gamma$  is introduced. In equation (6.11) we see that the full propagator is given by the free propagator and the self energy. In general the self energy is a complex quantity why they is splitted into real and imaginary part. With the free propagator in equation (6.7) the damped spin fermion propagator is given by

$$\mathcal{D}_{\mu}(\mathbf{k}, \omega) = \sum_{\mathbf{G}} \frac{1}{(\mathbf{k} + \mathbf{G})^2 + r - \xi^{-2} - i\gamma\omega} \quad (6.28)$$

where the abbreviation  $r = r_0 - \text{Re}\{\Pi_{\mu}(\mathbf{k}, \omega)\}$  is used. Remember that  $\xi$  represents the correlation length in this formula instead of the energy like it's used in the previous computation. At the quantum critical point the even introduced quantity  $r$  is zero. The real part of self energy is canceled with  $r_0$ . Further the investigated model is a low energy theory, why the correlation length  $\xi$ , which is proportional to  $\omega^2$  is neglectable.

### 6.3 Transformation of the Propagator on the Imaginary Axis

The spin density wave propagator obtained in the previous section is a complex function of the real quantity  $\omega$ . In the following the quantity  $\omega$  should be transformed

into an imaginary quantity  $i\omega_n$ , which we know as Matsubara frequencies. In this representation the computations in chapter 4 are much more convenient. The aim is now to find the real and imaginary part of the propagator with respect to the imaginary quantity  $i\omega_n$ . The Kramers-Kronig relations yield a relationship between the real part of a function and the imaginary part of the same function, or vice versa, where the argument of both parts is rotated by an arbitrary angle. In section 5.2.3 these relations are established, see (??) for the explicit form. The propagator in (6.28) can be easily separated into real and imaginary part

$$\mathcal{D}_\mu(\mathbf{k}, \omega) = \sum_{\mathbf{G}} \left[ \frac{(\mathbf{k} + \mathbf{G})^2}{(\mathbf{k} + \mathbf{G})^4 + (\gamma\omega)^2} + i \frac{\gamma\omega}{(\mathbf{k} + \mathbf{G})^4 + (\gamma\omega)^2} \right], \quad (6.29)$$

where  $r = \xi = 0$  is set. It is trivially seen that the real part is a symmetric function and the imaginary part is an antisymmetric function with respect to  $\omega$ . Similar to (6.28) the propagator  $\mathcal{D}_\mu(\mathbf{k}, i\omega_n)$  can be separated into a real and imaginary part. The imaginary part is zero, because the integrand in (??) is an antisymmetric function with respect to  $\omega$ . So the propagator with respect to Matsubara frequencies is given by

$$\mathcal{D}_\mu(\mathbf{k}, i\omega_n) = \frac{1}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega \frac{\text{Im}\{\mathcal{D}_\mu(\mathbf{k}, \omega)\}}{\omega - i\omega_n} \quad (6.30)$$

The integral is splitted into two parts and in the first term we substitute with  $\omega = -\omega$  and the antisymmetry of  $\text{Im}\{\mathcal{D}_\mu(\mathbf{k}, \omega)\}$  is utilized.

$$\begin{aligned} \mathcal{D}_\mu(\mathbf{k}, i\omega_n) &= \frac{1}{\pi} \int_0^{\infty} d\omega \text{Im}\{\mathcal{D}_\mu(\mathbf{k}, \omega)\} \left[ \frac{1}{\omega + i\omega_n} + \frac{1}{\omega - i\omega_n} \right] \\ \Leftrightarrow \mathcal{D}_\mu(\mathbf{k}, i\omega_n) &= \frac{2}{\pi} \sum_{\mathbf{G}} \int_0^{\infty} d\omega \frac{\gamma\omega}{(\mathbf{k} + \mathbf{G})^4 + (\gamma\omega)^2} \cdot \frac{\omega}{\omega^2 + \omega_n^2} \\ \Leftrightarrow \mathcal{D}_\mu(\mathbf{k}, i\omega_n) &= \sum_{\mathbf{G}} \frac{1}{(\mathbf{k} + \mathbf{G})^2 + \gamma|\omega_n|} \end{aligned} \quad (6.31)$$

In the last step the integral formula

$$\int_0^{\infty} dx \frac{x}{a^2 + x^2} \cdot \frac{x}{y^2 + x^2} = \frac{\pi}{2} \frac{1}{a + |y|} \quad (6.32)$$

is used, which can be shown by transforming into a complex contour integral.

## 7 Conclusion

# A Properties of the Kubo Relaxation Function

In section 5.2.2 the Kubo relaxation function

$$\Phi_{AB}(t) = \frac{i}{\hbar} \lim_{s \rightarrow 0} \int_t^{\infty} d\tau \langle [A_I(\tau), B_I(0)] \rangle_0 e^{-s\tau}. \quad (\text{A.1})$$

and the three relations

$$1. \quad \chi_{AB}(t) = -\Theta(t) \frac{d}{dt} \Phi_{AB}(t) \quad (\text{A.2})$$

$$2. \quad \Phi_{AB}(t=0) = \chi_{AB}(\omega=0) \quad (\text{A.3})$$

$$3. \quad \Phi_{AB}(\omega) = \frac{1}{i\omega} [\chi_{AB}(\omega) - \chi_{AB}(\omega=0)]. \quad (\text{A.4})$$

connecting the dynamical susceptibility  $\chi_{AB}$  with  $\Phi_{AB}$  are introduced. In the following we want to proof these three relations.

The first one is easily gotten by derivating the Kubo relaxation function with respect to  $t$  and comparing the result with the definition of the dynamical susceptibility (5.8).

$$-\Theta(t) \frac{d}{dt} \Phi_{AB}(t) = \frac{i}{\hbar} \Theta(t) \langle [A_I(t), B_I(0)] \rangle_0 = \chi_{AB}(t) \quad (\text{A.5})$$

The second relation is found with the aim of the Laplace transformation of the Kubo relaxation function.

$$\Phi_{AB}(\omega) = \int_0^{\infty} dt \Phi_{AB}(t) e^{i\omega t} \quad (\text{A.6})$$

In this definition of the Laplace transformation compared to (5.3) we set  $s = -i\omega$  which correspond to a rotation of  $\frac{\pi}{2}$  of the definition space . Using (A.6) after setting  $t = 0$  in (A.1) yield

reference to a book of laplace transformation

$$\begin{aligned} \Phi_{AB}(t=0) &= \frac{i}{\hbar} \lim_{s \rightarrow 0} \int_0^{\infty} d\tau \langle [A_I(\tau), B_I(0)] \rangle_0 e^{-s\tau} \\ \Leftrightarrow \Phi_{AB}(t=0) &= \frac{i}{\hbar} \lim_{\substack{s \rightarrow 0 \\ \omega \rightarrow 0}} \int_{-\infty}^{\infty} d\tau \Theta(\tau) \langle [A_I(\tau), B_I(0)] \rangle_0 e^{i\omega\tau} e^{-s\tau} \end{aligned}$$

$$\begin{aligned}
&\Leftrightarrow \Phi_{AB}(t=0) = \lim_{\omega \rightarrow 0} \int_{-\infty}^{\infty} d\tau \chi_{AB}(\tau) e^{i\omega\tau} \\
&\Leftrightarrow \Phi_{AB}(t=0) = \chi_{AB}(\omega=0),
\end{aligned} \tag{A.7}$$

where it is assumed the susceptibility is a good function in the sense they decay fast enough and the convergence generating faktor is negligible. The third relation is computed with the aim of the first and second relation. Therefore relation one is multiplied with  $e^{i\omega t}$  and is integrated with respect to  $t$ .

$$\begin{aligned}
&\int_0^{\infty} dt e^{i\omega t} \chi_{AB}(t) = - \int_0^{\infty} dt e^{i\omega t} \frac{d}{dt} \Phi_{AB}(t) \\
&\stackrel{\text{PI}}{\Leftrightarrow} \chi_{AB}(\omega) = -e^{i\omega t} \Phi_{AB}(t) \Big|_0^{\infty} + i\omega \int_0^{\infty} dt e^{i\omega t} \Phi_{AB}(t) \\
&\Leftrightarrow \chi_{AB}(\omega) = \Phi_{AB}(t=0) + i\omega \Phi_{AB}(\omega) \\
&\Leftrightarrow \Phi_{AB}(\omega) = \frac{1}{i\omega} [\chi_{AB}(\omega) - \chi_{AB}(\omega=0)]
\end{aligned} \tag{A.8}$$

In the first step the right hand side is integrated by parts and in last step the first relation and (A.6) is used. So the third relation gives us the dependence between the Kubo relaxation function and the dynamical susceptibility in frequency space.

## B Conversion of $(\dot{P} | (\omega - L_0)^{-1} | \dot{P})$

In this appendix the short conversion of the expectation value  $(\dot{P} | (\omega - L_0)^{-1} | \dot{P})$  is done. Therefore only realtions are used which we find in chapter 5. Firstly the expectation value is written as the correlation function in the frequency space using equation (5.45).

$$\begin{aligned}
& (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -i \mathcal{C}_{\dot{P}\dot{P}}(\omega) \\
& \stackrel{(A.6)}{\Leftrightarrow} (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -i \int_0^\infty dt e^{i\omega t} \mathcal{C}_{\dot{P}\dot{P}}(t) \\
& \stackrel{(5.42)}{\Leftrightarrow} (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -\frac{i}{\beta} \int_0^\infty dt e^{i\omega t} \int_0^\beta d\lambda \langle \dot{P}^\dagger(t) \dot{P}(0) \rangle \\
& \stackrel{(5.17)}{\Leftrightarrow} (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -\frac{i}{\beta} \Phi_{\dot{P}\dot{P}}(\omega) \\
& \stackrel{(5.12)}{\Leftrightarrow} (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -\frac{\omega^{-1}}{\beta} \left[ \chi_{\dot{P}\dot{P}}(\omega) - \underbrace{\chi_{\dot{P}\dot{P}}(\omega = 0)}_{=0} \right] \\
& \Leftrightarrow (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -\frac{\omega^{-1}}{\beta} \int_{-\infty}^\infty dt e^{i\omega t} \chi_{\dot{P}\dot{P}}(t) \\
& \stackrel{(5.8)}{\Leftrightarrow} (\dot{P} | (\omega - L_0)^{-1} | \dot{P}) = -\frac{i\omega^{-1}}{\hbar\beta} \int_0^\infty dt e^{i\omega t} \langle [\dot{P}(t), \dot{P}(0)] \rangle_0 \quad (B.1)
\end{aligned}$$

In line 5 the susceptibility at frequency  $\omega = 0$  is set to zero, because at  $\omega = 0$  the susceptibility corresponds to the Kubo relaxation function at  $t = 0$ . This function is zero because  $\dot{P} = 0$  at  $t = 0$ .

## C Fierz Identity

This appendix shows the use of the Fierz identity in relation to computing products of field operators connected via Pauli matrices. Lets signify the generators of the fundamental representation  $SU(N)$  as  $T^a$ , where those have the form

$$T_{ij}^a \quad \text{mit} \quad a = 1, 2, 3, \dots, N^2 - 1 \quad \text{and} \quad i, j = 1, 2, 3, \dots, N \quad (\text{C.1})$$

The Fierz identity yields the connection between the product of two generators and the Kronecker symbols. In general the Fierz identity is given by

$$\sum_{a=1}^{N^2-1} T_{ij}^a T_{kl}^a = \frac{1}{2} \left[ \delta_{il} \delta_{jk} - \frac{1}{N} \delta_{ij} \delta_{kl} \right] \quad (\text{C.2})$$

In the case of Pauli matrices the fundamental representation is  $SU(2)$  and the generator of  $SU(2)$  are connected with the Pauli matrices with the relation  $T^a = \frac{1}{2} \sigma^a$ . Therefore the Fierz identity for the fundamental representation is given by

$$4 \sum_{a=1}^3 T_{ij}^a T_{kl}^a = \sum_{a=1}^3 \sigma_{ij}^a \sigma_{kl}^a = 2\delta_{il} \delta_{jk} - \delta_{ij} \delta_{kl} \quad (\text{C.3})$$

Now this identity can be used for computing the fermionic expectation value obtained in section 6.2. In equation (??) the product of fermionic operators yields four terms of the structure

$$\text{EV}_F := \left\langle \Psi_\alpha^\dagger(\nu_1) \cdot \sigma^\mu \cdot \Psi_\beta(\nu_2) \cdot \Psi_\gamma^\dagger(\nu_3) \cdot \sigma^\mu \cdot \Psi_\delta(\nu_4) \right\rangle, \quad (\text{C.4})$$

where  $\alpha, \beta, \gamma, \delta \in \{a, b\}$  and has to be chosen with respect to the Fermi surface of the electrons. The explicite quantum numbers of the respected operators aren't important for the use of the Fierz identity, why the dummy quantity  $\nu_i$  with  $i = 1, 2, 3, 4$  is introduced. Firstly the product is written in component representation, which allows us to use the Fierz identity. In the expectation value above the sum over  $\mu$  should be implied.

$$\begin{aligned} \text{EV}_F &= \left\langle \left( \Psi_\alpha^\dagger(\nu_1) \right)_i \cdot \sigma_{ij}^\mu \cdot \left( \Psi_\beta(\nu_2) \right)_j \cdot \left( \Psi_\gamma^\dagger(\nu_3) \right)_k \cdot \sigma_{kl}^\mu \cdot \left( \Psi_\delta(\nu_4) \right)_l \right\rangle \\ \Leftrightarrow \text{EV}_F &= \sigma_{ij}^\mu \sigma_{kl}^\mu \left\langle \left( \Psi_\alpha^\dagger(\nu_1) \right)_i \left( \Psi_\beta(\nu_2) \right)_j \left( \Psi_\gamma^\dagger(\nu_3) \right)_k \left( \Psi_\delta(\nu_4) \right)_l \right\rangle \\ \Leftrightarrow \text{EV}_F &= (2\delta_{il} \delta_{jk} - \delta_{ij} \delta_{kl}) \left\langle \left( \Psi_\alpha^\dagger(\nu_1) \right)_i \left( \Psi_\beta(\nu_2) \right)_j \left( \Psi_\gamma^\dagger(\nu_3) \right)_k \left( \Psi_\delta(\nu_4) \right)_l \right\rangle \end{aligned}$$

$$\begin{aligned}
\Leftrightarrow \text{EV}_F &= 2 \left\langle \left( \Psi_\alpha^\dagger(\nu_1) \right)_i \delta_{il} \left( \Psi_\delta(\nu_4) \right)_l \left( \Psi_\beta(\nu_2) \right)_j \delta_{jk} \left( \Psi_\gamma^\dagger(\nu_3) \right)_k \right\rangle \delta_{\nu_3, \nu_4} \\
&\quad - \left\langle \left( \Psi_\alpha^\dagger(\nu_1) \right)_i \delta_{ij} \left( \Psi_\beta(\nu_2) \right)_j \left( \Psi_\gamma^\dagger(\nu_3) \right)_k \delta_{kl} \left( \Psi_\delta(\nu_4) \right)_l \right\rangle \\
\Leftrightarrow \text{EV}_F &= 2 \left\langle \Psi_\alpha^\dagger(\nu_1) \Psi_\delta(\nu_4) \Psi_\beta(\nu_2) \Psi_\gamma^\dagger(\nu_3) \right\rangle \delta_{\nu_3, \nu_4} - \left\langle \Psi_\alpha^\dagger(\nu_1) \Psi_\beta(\nu_2) \Psi_\gamma^\dagger(\nu_3) \Psi_\delta(\nu_4) \right\rangle
\end{aligned} \tag{C.5}$$

The use of the Fierz identity has eliminated the Pauli matrices in our expression of the expectation value. Instead we get two expectation values with a different order of the field operators. Now let us investigate what happens with the fermionic expectation values in the second order of perturbation theory. In the corresponding expectation values are always two fermionic operators of the same electron family a or b. This means that always two greek letters have to be set to a and the other two ones to b in equation (C.5). The expectation values of different electron families can be separated without any doubt, because their Hilbert spaces are disconnected. For this reason many combinations of choosing the greek letters are zero. Let us demonstrate this with an example. If we choose  $\alpha = \gamma = a$  and the other two ones respectively to b, then an expectation value emerges with two fermionic creation operators and another one emerges with two fermionic annihilation operators, which is always zero. For the fermionic expectation value  $\text{EV}(\mathcal{D})$  in equation (??) this procedure yields

$$\begin{aligned}
\text{EV}(\mathcal{D}) &= \left\langle \mathcal{T}_t \Psi_a(\tilde{\mathbf{p}}_2, t_1) \Psi_a^\dagger(\tilde{\mathbf{p}}_3, t_2) \right\rangle \left\langle \mathcal{T}_t \Psi_b(\tilde{\mathbf{p}}_4, t_2) \Psi_b^\dagger(\tilde{\mathbf{p}}_1, t_1) \right\rangle \delta_{\tilde{\mathbf{p}}_2 - \tilde{\mathbf{p}}_3} \delta_{\tilde{\mathbf{p}}_4 - \tilde{\mathbf{p}}_1} \\
&\quad + \left\langle \mathcal{T}_t \Psi_b(\tilde{\mathbf{p}}_2, t_1) \Psi_b^\dagger(\tilde{\mathbf{p}}_3, t_2) \right\rangle \left\langle \mathcal{T}_t \Psi_a(\tilde{\mathbf{p}}_4, t_2) \Psi_a^\dagger(\tilde{\mathbf{p}}_1, t_1) \right\rangle \delta_{\tilde{\mathbf{p}}_2 - \tilde{\mathbf{p}}_3} \delta_{\tilde{\mathbf{p}}_4 - \tilde{\mathbf{p}}_1}
\end{aligned} \tag{C.6}$$
